

Benchmarking Intensity

Anna Pavlova* and Taisiya Sikorskaya†

March 15, 2021

Abstract

A fund manager evaluated relative to a benchmark index optimally invests a fraction of the fund's assets under management (AUM) in her benchmark, and such demand is inelastic. Using a dataset of 34 U.S. equity indices, we construct a stock-level measure of benchmarking intensity (BMI), which captures the inelastic component of fund managers' demand. The BMI of a stock is computed as the cumulative weight of the stock in all benchmarks, weighted by AUM following each benchmark. We exploit a variation in the BMIs of stocks that transition between the Russell 1000 and Russell 2000 indices and document the following. First, stocks with a larger change in BMI experience a larger price increase in an index reconstitution. Second, by capturing the inelastic demand of passive and active managers, as opposed to only passive, we compute the price elasticity of demand more accurately than in the index effect literature. Third, using fund holdings around the Russell 1000/2000 index cutoff, we present evidence of inelastic demand of active managers for stocks in their benchmarks. Finally, we confirm the prediction of our theory that stocks with higher BMIs have lower long-run returns. A parallel test based on analysts' estimates of the cost of equity shows that a firm with a higher BMI has a lower cost of equity.

1 Introduction

The asset management industry has been growing in size and importance over time. As of 2018, it has amassed more than \$74 trillion¹ in assets under management (AUM). A large fraction of these funds are managed against benchmarks (e.g., the S&P 500, FTSE-Russell indices, etc.). Benchmarks convey to end investors information about the types of stocks a fund invests in and act as a useful tool for performance evaluation of fund managers. With growing investor appetite for different investment styles, benchmarks are becoming increasingly heterogeneous. In 2018, the AUM share of U.S. mutual funds benchmarked to S&P 500 was 35%, the next 34% was split between the Russell indices, followed by 22% benchmarked to the CRSP indices.² Our objective is to link membership in multiple benchmarks to stock prices and expected returns, as well as demand by fund managers.

In this paper, we argue that stocks included in a benchmark form a preferred habitat for fund managers evaluated against that benchmark. In our model, benchmarked fund managers have an incentive to hold stocks in their benchmarks, which makes a fraction of their demand for these stocks inelastic. We derive a measure, which we term the *benchmarking intensity* (BMI), that captures the aggregate inelastic demand of all benchmarked managers. We define the benchmarking intensity of a stock as the cumulative weight of the stock in all benchmarks, weighted by assets under management following each benchmark. For the former, we use the historical composition of 34 U.S. equity indices. For the latter, we use the AUM of U.S. equity mutual funds. We scrape the website of the U.S. Securities and Exchange Commission to extract the history of fund benchmarks directly from prospectuses which are available as unstructured text.³

We exploit the variation in the benchmarking intensity of stocks that transition across the Russell 1000/2000 index cutoff to establish the effects of BMI on stock prices, expected returns, fund ownership, and demand elasticities. First, we show that the change in BMI resulting from an index reconstitution is positively related to the size of the index effect. Second, we argue that a change in BMI corresponds to the overall change in inelastic demand for a stock. Specifically, it accounts for both active and passive managers' demand and for all relevant benchmarks that include this stock, which allows us to measure demand elasticities more accurately than in the literature. Third, we highlight that active managers contribute

¹Based on BCG report, <https://www.bcg.com/en-gb/publications/2019/global-asset-management-will-these-20s-roar.aspx>.

²Figure 5 in the Appendix plots assets under management of US domestic equity mutual funds, by benchmark. The heterogeneity of benchmarks is apparent from the figure, especially for mid-cap and small stocks.

³Details of the procedure and methods used to validate our benchmark data are described in the text. Previous research has used a snapshot of fund benchmarks or assumed S&P 500 as a universal benchmark.

substantially to the benchmarking intensity and document that they buy additions to their benchmarks and sell deletions. Their purchases of additions to the benchmark, which have gone up in price, indicate that their demand for stocks in their benchmark contains an inelastic component. Finally, we confirm the prediction of our theory that stocks with higher benchmarking intensities have higher prices and lower expected returns. In particular, we show that an increase in a stock’s benchmarking intensity leads to underperformance relative to comparable stocks for a period of one to five years. The literature has only considered shorter-term ‘reversals’ of the index inclusion effect, attributing this pattern to limits to arbitrage, while we argue that index membership permanently lowers the risk premium on a stock due to the inelastic demand of fund managers investing in it.

We start with a simple model that highlights the channel through which a stock’s benchmarking intensity affects its price and expected return. The model features fund managers alongside standard direct investors. All investors are risk-averse. A fund manager’s compensation depends on performance relative to her benchmark. The model predicts that such performance evaluation makes benchmark stocks the preferred habitat of managers evaluated against that benchmark. The fund manager’s higher demand for her benchmark stocks makes prices of these stocks higher in equilibrium and their expected returns lower. This effect is permanent, persisting for as long as the stocks remain in the benchmark. In an equilibrium with heterogeneous benchmarks, the variable that captures the additional (inelastic) demand of benchmarked managers – beyond what the standard risk-return trade-off would predict – is exactly the benchmarking intensity.

In our empirical analysis, we focus on differences in BMI in the cross-section of stocks. Isolating the effects of this variation is challenging. Stocks with higher benchmarking intensities are included in more benchmarks and have larger weights in them. Since most of the benchmarks are value-weighted, larger firms have higher BMIs. These larger firms tend to have lower returns due to the size effect. They also tend to carry a liquidity premium. There may be other confounding effects if one simply compares stocks in major benchmarks (with higher BMIs) to those that are not. Our solution to these challenges is to exploit the cutoff between the Russell 1000 and 2000 indices, which separates stocks that are very similar in size and other characteristics but differ significantly in terms of their benchmarking intensities. Mechanical index reconstitution rules lead to the close-to-random index assignment into the Russell 1000 and 2000 indices, which serves as a source of (conditionally) exogenous variation in the benchmarking intensity. We perform our analysis on stocks added to or deleted from the Russell 2000, using stocks close to the cutoff that do not switch indices as the control group.

We empirically link the size of the price pressure experienced by a stock to the change

in its benchmarking intensity. Corroborating the results of [Chang et al. \(2014\)](#), we document price pressure upon index reconstitution (the index effect). As in the index effect literature, [Chang et al.](#) look only at the average effect.⁴ Our contribution is to show that the higher the change in BMI, the larger the size of the index effect in the cross-section.

BMI allows us to measure the price elasticity of demand more precisely than in the related literature. The majority of the literature has exploited index reconstitutions to measure the price elasticity of demand using the change in passive assets as a shock to net supply. If active managers' demand features an inelastic component, measures of elasticity based on a passive demand change upon index reconstitution will be inaccurate. We show that the increase in BMI is a more appropriate measure of the reduction in effective supply of shares due to index reconstitution because it reflects the increase in total inelastic demand. We also argue that accounting for heterogeneous benchmarks (e.g., that each Russell 1000 stock also belongs to the Russell 1000 Value and/or Growth, and often to the Russell Midcap) is important when estimating the elasticity of demand for stocks.

We show that both active and passive investors have a considerable fraction of holdings concentrated in their benchmarks and that their rebalancing around the Russell cutoffs is consistent with changes to their benchmarks. The majority of recent studies attributed the discontinuities in ownership around the cutoff to passive investors, i.e., index and exchange-traded funds. In line with the literature, we find highly significant rebalancing of index additions and deletions for passive funds in the direction imposed by their benchmarks. For example, passive funds benchmarked to the Russell 2000 purchase additional 112bps of shares of stocks added to the Russell 2000. These funds also sell deleted stocks in similar proportions. Using the data on funds' benchmarks, we are able to demonstrate the same pattern in active funds. We find that active funds benchmarked to the Russell 2000 also sell deletions, decreasing their ownership share by 46bps. Active funds benchmarked to the Russell 1000 and Russell Midcap increase their ownership shares in stocks added to the Russell 1000 and Midcap by 9bps and 20bps, respectively. So in line with our theory, stocks inside the benchmarks serve as both active and passive funds' preferred habitats.

We conduct one further test to uncover the inelastic component in the demand function of active managers. Using our model's prediction on the relationship between BMI and index effect, we empirically separate the elastic and inelastic responses of active funds to the index reconstitution. We find that the elastic response is small and rarely significant, while the inelastic response is robust across benchmarks.

We also find that, consistent with our theory, stocks with higher benchmarking inten-

⁴The exceptions are [Greenwood \(2005\)](#) and [Wurgler and Zhuravskaya \(2002\)](#) who link the size of the index effect to arbitrage risk.

sities have lower long-run returns. Increased inelastic demand of benchmarked fund managers indeed leads to significantly lower expected returns of these stocks for horizons of up to 5 years. This result is robust to alternative specifications and we point out that its size depends on whether stocks switching indices multiple times are excluded from the sample, as our theory would suggest. We can interpret our finding as a negative long-run return of a long-short portfolio that buys stocks with high BMIs and sells stocks with low BMIs.

Related research. This paper is related to several strands of literature, including equilibrium asset pricing with benchmarked fund managers, index effect, and empirical research on the effects of institutional ownership.

Among theoretical contributions, the first paper to study benchmarking is [Brennan \(1993\)](#). [Brennan](#) derives a two-factor asset pricing model in a two-period economy with a benchmarked fund manager. [Cuoco and Kaniel \(2011\)](#), [Basak and Pavlova \(2013\)](#) and [Buffa et al. \(2014\)](#) investigate equilibrium asset pricing effects of delegated portfolio management in dynamic economies. The closest paper to ours in this strand of literature is [Kashyap et al. \(2020a\)](#). None of these works, however, considers heterogeneous benchmarks. The only paper that does is [Buffa and Hodor \(2018\)](#), but they focus primarily on asset return comovement. In our model, heterogeneous habitats of fund managers arise because of the heterogeneity in benchmarks. Such habitats could also be driven by optimal narrow investment mandates in delegated asset management (e.g., [van Binsbergen et al. \(2008\)](#), [He and Xiong \(2013\)](#)) or different investor styles ([Barberis and Shleifer \(2003\)](#)). A related idea of studying how investor habitats affect asset prices is explored in preferred habitat models of the term structure of interest rates (e.g., [Vayanos and Vila \(2020\)](#)).

Both our theoretical and empirical results are related to the index effect literature. The index effect was first documented by [Shleifer \(1986\)](#) and [Harris and Gurel \(1986\)](#) for additions to the S&P 500 index and subsequently found in many other markets and asset classes.⁵ This literature typically measures the average size of index effect, while we show how it differs in the cross-section depending on the BMI.

The existence of the index effect challenges the standard theories, which predict that demand curves for each stock are very elastic and therefore index inclusion should have no effect on asset prices and expected returns. The index effect literature has converged to the view that stocks are not perfect substitutes, which suggests that the demand curves for

⁵Most of the studies focus on S&P 500 and Russell composition changes, though others also cover such index families as MSCI, DJIA, Nikkei, FTSE, CAC, Toronto Stock Exchange Index, etc. For example, [Chen et al. \(2005\)](#) document a long-lasting price increase of the S&P 500 additions, which increases in magnitude through time. [Hacibedel and van Bommel \(2007\)](#) also find permanent price increase for emerging markets indices within the MSCI family. [Greenwood \(2005\)](#) documents an index effect for a redefinition of the Nikkei 225 index in Japan.

stocks are downward-sloping. Our preferred habitat model provides a microfoundation for why stocks are imperfect substitutes.⁶ In the model, fund managers’ demand features an inelastic part due to benchmarking. This affects stock prices and expected returns for as long as the stocks remain in the benchmark.

Our analysis delivers an alternative estimate of stock price elasticity of demand based on an index inclusion event. Most of the known estimates are based on a single index membership, while our BMI measure accounts for the demand related to all large benchmarks in a comprehensive way. Furthermore, the change in stock’s BMI helps measure the price elasticity of demand more accurately in a world where active managers’ demand has both elastic and inelastic components. Recent literature stresses the importance of incorporating downward-sloping demand curves for stocks in the asset pricing and macro-finance models (for example, [Gabaix and Koijen \(2020\)](#)), and our results may inform such models.

The closest empirical work to ours is [Chang et al. \(2014\)](#). It is the first paper to build a regression discontinuity design (RDD) on the cutoff between the Russell 1000 and 2000 indices in order to quantify the price pressure stemming from institutional demand. The paper finds a 5% index effect in the month of addition to and deletion from the Russell 2000. It also documents a decreasing trend in this index effect and attributes it to the alleviation of limits to arbitrage. Even though we use the same cutoff for identification, we are the first to document the resulting difference in the long-run returns (twelve months to five years) of stocks that moved indices and those that did not. We view the duration of this effect as evidence that index membership affects the risk premium of a stock. We rule out cash-flow based and other explanations of our results. Furthermore, we explain the variation in the size of the index effect in the cross-section and link it to the BMI. We also discuss how [Chang et al.](#)’s estimates of demand elasticity change in a setting with heterogeneous benchmarks.

There is a growing body of literature studying implications of passive ownership for corporate governance using the Russell cutoff.⁷ This literature documents predictable rebalancing of passive funds around the cutoff, but not active. In line with the findings of this literature, we find that the *total* active ownership in stocks that switched indices does not change. However, our granular data allows us to show that the identities of active funds change as benchmarks would predict. For example, a stock that is deleted from the Russell 2000 is sold by the active funds benchmarked to the Russell 2000 and bought by active funds benchmarked to the Russell 1000 and Midcap. As a result, monitoring incentives of active managers may change and this may affect corporate governance.

⁶[Petajisto \(2009\)](#) offers a complementary view, also based on asset manager demand.

⁷The list of papers includes but is not limited to: [Appel et al. \(2019b\)](#), [Glossner \(2018\)](#), [Heath et al. \(2018\)](#), [Schmidt and Fahlenbrach \(2017\)](#), [Appel et al. \(2016\)](#).

The paper proceeds as follows. Section 2 explains the implications of heterogeneous benchmarks for stock returns. In Section 3, we construct the measure of benchmarking intensity, show how it is linked to the size of the index effect and the elasticity of demand. We discuss funds' preferred habitats and rebalancing in Section 4. In Section 5, we inspect the relationship between BMI and long-run returns. Omitted details and further robustness exercises are relegated to the Appendix.

2 Model of Delegated Asset Management with Heterogeneous Benchmarks

To illustrate the main mechanism, we first develop a simple model of asset prices in the presence of benchmarking. It builds upon Brennan (1993) and Kashyap et al. (2020a) and introduces heterogeneous fund managers whose performance is evaluated relative to a variety of benchmarks. The goal of the model is to characterize a relationship between benchmarking intensity, our measure of capital that is inelastically supplied by fund managers, and stock returns.

2.1 Model

Except for the presence of fund managers, our environment is standard. There are two periods, $t = 0, 1$. The financial market consists of a riskless asset with an exogenous interest rate normalized to zero (e.g., a storage technology) and N risky assets paying cash flows D_i , $i = 1, \dots, N$ in period 1. The cash flows of the risky assets are given by

$$D_i = \bar{D}_i + \beta_i Z + \epsilon_i, \quad c_i > 0, \quad i = 1, \dots, N,$$

where $Z \sim N(0, \sigma_z^2)$ is a common shock and $\epsilon_i \sim N(0, \sigma_\epsilon^2)$ is an idiosyncratic one. The vectors $D \equiv (D_1, \dots, D_N)^\top$ and $S \equiv (S_1, \dots, S_N)^\top$ denote vectors of period-1 cash flows and period-0 risky asset prices, respectively. Period-1 risky asset prices equal D . The risky assets are in fixed supply of $\bar{\theta} \equiv (\bar{\theta}_1, \dots, \bar{\theta}_N)$ shares. It is convenient to introduce the notation $\Sigma \equiv \Sigma_z + I_N \sigma_\epsilon^2$ for the variance-covariance matrix of cash flows D , where Σ_z is a $N \times N$ matrix with a typical element $\beta_i \beta_j \sigma_z^2$ and I_N is an $N \times N$ identity matrix. We also set $\bar{D} \equiv (\bar{D}_1, \dots, \bar{D}_N)^\top$ and $\beta \equiv (\beta_1, \dots, \beta_N)^\top$.

There are J benchmark portfolios that are used for performance evaluation. Each benchmark j is a portfolio of $\omega_j \equiv (\omega_{1j}, \dots, \omega_{Nj})^\top$ shares of the assets described above. Some components of ω_j can be zero.

There are two types of investors: direct investors and fund managers. Direct investors, whose mass in the population is λ_D , manage their own portfolios. Fund managers manage portfolios on behalf of fund investors. Fund investors can buy the riskless asset directly, but cannot trade stocks; they delegate the selection of their portfolios to portfolio managers. The managers receive compensation from fund investors. Each manager is evaluated relative to a benchmark. We denote the mass of managers evaluated relative to benchmark j by λ_j .⁸ All investors have a constant absolute risk aversion utility function over terminal wealth (or compensation), $U(W) = -\exp^{-\gamma W}$, where γ is the coefficient of absolute risk aversion.

The terminal wealth of a direct investor is given by $W = W_0 + \theta_D^\top(D - S)$, where the $N \times 1$ vector θ_D denotes the number of shares held by the direct investor, and W_0 is the investor's initial wealth. The direct investor chooses a portfolio θ_D to maximize his utility $U(W)$. A fund manager's j compensation w_j consists of three parts: one is a linear payout based on absolute performance of the fund, the second piece depends on the performance of the fund relative to the benchmark portfolio j , and the third is independent of performance (c). Specifically,

$$w_j = aR_j + b(R_j - B_j) + c, \quad a \geq 0, b > 0$$

where $R_j \equiv \theta_j^\top(D - S)$ is the performance of the fund's portfolio and $B_j \equiv \omega_j^\top(D - S)$ is the performance of benchmark j .⁹ The parameters a and b are the contract's sensitivities to absolute and relative performance, respectively. The fund manager chooses a portfolio of θ_j shares to maximize his utility $U(w_j)$.

2.2 Portfolio Choice and Asset Prices

The optimal portfolio of the direct investors is the standard mean-variance portfolio:¹⁰

$$\theta_D = \frac{1}{\gamma} \Sigma^{-1} (\bar{D} - S). \quad (1)$$

In contrast, the fund managers do not have the same risk-return trade-off as direct investors, because of their compensation contracts. The optimal portfolio of manager j is given by

$$\theta_j = \frac{1}{\gamma(a+b)} \Sigma^{-1} (\bar{D} - S) + \frac{b}{a+b} \omega_j. \quad (2)$$

⁸For simplicity, we assume that each fund investor employs one fund manager, but this can easily be relaxed.

⁹Ma et al. (2019) analyze compensation of fund managers in the US mutual fund industry and provide evidence supporting our specification here. Endogenizing this compensation structure is beyond the scope of this paper; see Kashyap et al. (2020b) who derive it as part of an optimal contract.

¹⁰We omit proofs in the main text and relegate them to Appendix B, available upon request.

The fund manager splits his risky asset holdings across two portfolios: the mean-variance portfolio (the first term in (2)) and the benchmark portfolio (the second term). The latter portfolio arises because the manager hedges against underperforming the benchmark. Consistent with the preferred habitat view, the manager thus has a higher demand for stocks in her benchmark. Notice that the demand for the benchmark portfolio ω_j is inelastic. It does not depend on the riskiness of the assets and depends only on the parameters of the compensation contract. It follows that, *ceteris paribus*, stocks with a higher benchmark weight have a higher weight in the fund manager's portfolio.

By clearing markets for the risky assets, $\lambda_D \theta_D + \sum_{j=1}^J \lambda_j \theta_j = \bar{\theta}$, we compute equilibrium asset prices.

$$S = \bar{D} - \gamma A \Sigma \left(\bar{\theta} - \frac{b}{a+b} \sum_{j=1}^J \lambda_j \omega_j \right), \quad (3)$$

where $A \equiv \left[\lambda_D + \frac{\sum_j \lambda_j}{a+b} \right]^{-1}$ modifies the market's effective risk aversion.¹¹

Equation (3) elucidates the determinants of the index effect in our model. The index effect manifests itself through the benchmarking-induced price pressure term $\frac{b}{a+b} \sum_{j=1}^J \lambda_j \omega_j$. This term reflects the cumulative inelastic demand of fund managers and motivates our benchmarking intensity measure used in the empirical part of the paper. Equation (3) implies that if a stock gets added to a benchmark or if its weight in a benchmark increases, its price goes up. Another implication is that the larger the mass of fund managers (λ_j 's) following a benchmark, the higher the benchmarking-induced price pressure and hence the bigger the index inclusion effect. The more benchmarks a stock belongs to and the bigger its weight in the benchmarks, the more demand from fund managers it attracts and therefore the higher the stock's price.

Our next set of predictions is about the expected stock returns (or the cost of equity). The expected return of stock i , expressed as a per-dollar return $E[r_i] \equiv (\bar{D}_i - S_i)/S_i$, is given by

$$E[r_i] = \frac{\gamma A}{S_i} \beta_i \sigma_z^2 \beta^\top \left(\bar{\theta} - \frac{b}{a+b} \sum_{j=1}^J \lambda_j \omega_j \right) + \frac{\gamma A}{S_i} \sigma_\epsilon^2 \left(\bar{\theta}_i - \frac{b}{a+b} \sum_{j=1}^J \lambda_j \omega_{ij} \right) \quad (4)$$

Equation (4) implies that the price pressure we discussed above is permanent, and it lasts

¹¹ Our model can be extended to incorporate passive managers, who simply hold the benchmark portfolio. Suppose the total mass of fund managers benchmarked to index j , λ_j , consists of a mass λ_j^P of passive managers and a mass λ_j^A of active. Then the expression for stock prices is:

$$S = \bar{D} - \gamma A \Sigma \left(\bar{\theta} - \sum_{j=1}^J \left[\frac{b}{a+b} \lambda_j^A \omega_j + \lambda_j^P \omega_j \right] \right), \text{ where } A \equiv \left[\lambda_D + \frac{\sum_j \lambda_j^A}{a+b} \right]^{-1}.$$

for as long as a stock remains in the fund managers’ benchmarks. Therefore, *ceteris paribus*, stocks with higher benchmarking intensities, defined in our model as $\sum_{j=1}^J \lambda_j \omega_{ij}$, have lower expected returns. Furthermore, if a stock’s benchmarking intensity goes up (e.g., due to an index inclusion), its price should rise upon announcement and the expected return after the announcement should be lower.

In summary, our model produces the following predictions:

Prediction 1: Stocks with higher benchmark intensities have lower expected returns.

Prediction 2: If a stock’s benchmarking intensity goes up (e.g., due to an index inclusion), its price should rise.

Prediction 3: If a stock’s benchmarking intensity goes up, the funds’ ownership of the stock ($\sum_j \theta_{ij}$) should rise.

3 Empirical Analysis

3.1 Dataset

The main sample is a yearly panel of stocks which were the Russell 3000 constituents in 1998-2018.¹² The main three pillars of data are historical benchmark weights, mutual fund holdings, and stock characteristics. The second and third are standard, we report details on them in Section A.2 of Appendix.

In contrast to the previous studies, the dataset is granular with respect to benchmark information. It includes primary prospectus benchmarks scraped directly from historical fund prospectuses available on the website of the U.S. Securities and Exchange Commission¹³ and augmented with a Morningstar snapshot. The scraping procedure and its validation are described in detail in Section A.3 in the Appendix. We obtain benchmark constituent data from the following sources. All the constituent weights for 22 Russell benchmark indices are from FTSE Russell (London Stock Exchange Group). The Russell indices include (all total return in USD): Russell 1000, 2000, 2500, 3000, 3000E, Top 200, Midcap, Small Cap Completeness (blend) as well as their Growth and Value counterparts. Constituent weights for the S&P 500 TR USD and S&P MidCap 400 TR USD are from Morningstar and available from September 1989 and September 2001, respectively, to October 2015. We construct constituent weights for S&P 500 before September 1989 and after October 2015 manually

¹²Our main sample starts in 1998 because before that we do not have benchmark data of sufficient quality. Even though the SEC’s electronic archives date back to 1994, many funds do not report their benchmarks in files available prior to 1998. Please find the details in Section A.3. Our sample ends in December 2018 because the holdings data used for the analysis of fund ownership is available with a lag.

¹³Follow <https://www.sec.gov/edgar/searchedgar/mutualsearch.html>

from constituent lists and prices available through CRSP. We generate the S&P 400 weights from holdings of index funds (Dreyfus and iShares).¹⁴ The constituent weights for the CRSP US indices are from Morningstar and available from 2012. These indices include (all total return in USD): Total Market, Large Cap, Mid Cap, Small Cap (blend) as well as their Growth and Value counterparts.

Our benchmark data has two advantages to prior research. First, the benchmark information is a dynamic panel encompassing benchmark changes.¹⁵ Therefore, it accurately reflects the benchmark used by funds at any point in time.¹⁶ Secondly, we obtain Russell index data from FTSE Russell directly: our dataset includes proprietary total market values (capitalization) as of the rank day in May and provisional constituent lists available before the reconstitution day in June.

We report the descriptive statistics of the main calculated variables used in analysis in Table 8 in the Appendix.

3.2 Empirical Measure of Benchmarking Intensity

Guided by the model, we calculate the *benchmarking intensity* (BMI) for stock i in month t as

$$BMI_{it} = \sum_{j=1}^J \lambda_{jt} \omega_{ijt}$$

where λ_{jt} is the assets under management (AUM) of mutual funds benchmarked to index j as a fraction of the total equity market cap in month t ¹⁷ and ω_{ijt} is the weight of stock i in index j in month t . Importantly, BMI computation does not rely on holdings data. Holdings data are available at best quarterly and can be noisy while index composition and AUM are observed monthly.

Because the largest market indices are value-weighted, BMI is closely tied to the market cap of the company. In the literature, firm size was related to stock returns, which poses a challenge for our empirical analysis.

¹⁴Since the S&P 400 index is relatively small, these weights do not contribute much to the analysis. We do not include the S&P 600 index because its share is even smaller and the holdings-based weights are not of sufficient quality.

¹⁵See Appendix, in which we show that our scraping procedure picked up such important benchmark changes as Vanguard’s move from the MSCI to CRSP indices in 2013.

¹⁶We attribute funds with benchmarks with non-value weighted constituents and SRI screened funds to their ‘parent’ benchmarks, e.g. the S&P 500 equal-weighted index to the S&P 500 index. These funds are small in our sample and removing them does not change the results.

¹⁷BMI can also be defined using the total mutual fund assets in the denominator; our results are qualitatively the same. We also experimented with scaled AUM shares. For example, we used shares scaled to the industry AUM in 2014 as it is the time when the CRSP indices were introduced, completing our universe of benchmarks.

Even though benchmarking intensity is typically slow-moving, considerable variation comes from index membership. If a stock switches indices, for example, moves out of the S&P 500 index, its BMI changes. A useful illustration is a natural gas company Range Resources Corp. (ticker *RRC*). Figure 1 depicts a year-on-year evolution of its benchmarking intensity. Despite the evident comovement between size and benchmarking intensity, the latter has more variation due to the changing index membership and index asset flows: in 2005 *RRC* joins the Russell 1000 and Russell Midcap, in 2008 – the S&P 500, in 2012 *RRC* gets into the CRSP Mid Cap, in 2018 it exits the S&P 500 and gets added to S&P 400 and the CRSP Small Cap.

Figure 1: Benchmarking Intensity of *RRC*

This figure plots the benchmarking intensity (left axis) and the total market value (right axis) of *RRC* stock over time. Arrows point to the years when the stock was added to the benchmarks. Total market value is scaled by 2,500.

Figure 2 illustrates the contribution of membership in each index to the benchmarking intensity of *RRC* (Panel (a)). Even though most of the time the stock’s S&P 500 membership contributes over 50%, the size and variation of other components are significant. Panel (b) of the same Figure shows how much different benchmark styles (i.e., value, growth, and blend) contribute to *RRC*’s BMI. In our data, we only have style indices for the Russell and CRSP families, so the rest is attributed to blend. Even with this limitation, it is apparent that style benchmarks occupy a considerable fraction of BMI. These two illustrations highlight one of the key contributions of our measure – it takes into account the heterogeneity of benchmarks and overlaps between them.

Since the benchmarking intensity measure is built using the AUM of both active and passive funds, there is a variation coming from the relative importance of these two fund

types as depicted in Panel (c) of Figure 2. The BMI of *RRC* is dominated by the inelastic demand from active funds, which changes in 2018 as the stock exits the S&P 500 universe. This illustrates another important contribution of BMI – unlike passive ownership, a measure of institutional demand used in the extant literature – the BMI accounts for the inelastic demand of active funds as well.

Table 1 documents descriptive statistics for BMI in our sample. S&P 500 stocks have the highest average BMI, while the BMI of almost all Russell 2000 stocks is below the sample average. The reported statistics also highlight the increasing heterogeneity of benchmarks for U.S. equities: the average number of benchmarks increased from 7 to 10 and the benchmark Herfindahl-Hirschman index went down from 1100 to 740. Together, value and growth indices are at least as important as blend indices, contributing on average almost 60% to the BMI. Furthermore, active funds contribute 83% to the BMI over the full sample period, even though their share declined to an average of 65% in the recent 5 years.

BMI is not free of limitations. Empirically, we only observe benchmarks of the U.S. funds, while U.S. firms have seen an increasing share of foreign owners. This implies that the BMI we compute is a proxy of the true BMI which should include foreign funds benchmarked to U.S. stock indices. On the theory side, we assume that there are no transaction costs and fund mandates only differ in the benchmark used. In practice, however, trading is costly and funds may have other constraints, such as bounds on sector exposure. This is expected to skew the weights used to compute BMI. We discuss the consequences of considering trading costs at the end of Section 5.2.

Figure 2: Decomposition of the Benchmarking Intensity of RRC

These figures plot the evolution of each component of the benchmarking intensity of RRC stock over time. Figure (a) plots index groups, each including blend, value, and growth indices. Figure (b) plots Russell and CRSP style components. Figure (c) plots the contribution of active and passive funds.

Table 1: Properties of benchmarking intensity

	By time period					By benchmark					
	Full sample	1998-2000	2001-2006	2007-2012	2013-2018	S&P 500	Russell 1000	Russell 2000	Russell Midcap	Russell Value indices	Russell Growth indices

This table reports the descriptive statistics for benchmarking intensity. Columns ‘By time period’ show statistics for the respective period. Columns ‘By benchmark’ show statistics for stocks that belong to the respective benchmark. BMI statistics (average, standard deviation, minimum, and maximum) are in basis points. Contribution is in percentage points. Contribution of indices is average of the ratios of BMI coming from the AUM benchmarked to an index to total BMI of the stock. Contribution of indices is across index styles, e.g., line for the Russell 1000 includes blend, value, and growth. Average number of benchmarks is for a stock. Benchmark HHI is a Herfindahl-Hirschman index computed using benchmark AUM shares (scaled by 10000, so that index below 1500 indicates an unconcentrated industry). Averages are simple arithmetic means across stock-years.

3.3 Benchmarking Intensity and the Price Elasticity of Demand

In this section, we explore the relationship between the benchmarking intensity, the size of the index effect, and demand elasticity. We exploit the cutoff between the Russell 1000 and 2000 indices, which separates stocks that are very similar in size and other characteristics but differ significantly in terms of their benchmarking intensities. The close-to-random index assignment into the Russell 1000 and 2000 indices serves as a source of (conditionally) exogenous variation in the benchmarking intensity.

3.3.1 The Russell Index Cutoff

BMI is computed using all equity indices at any point in time. However, there is a range of stocks with similar size but different BMIs due to the cutoff between Russell 1000 and 2000 indices.

The Russell indices undergo an annual reconstitution every June. All eligible stocks get ranked based on their market cap value, and the top 1000 stocks get assigned to Russell 1000. The ranking is based on a fixed date in May so any shock to a stock next to the cutoff can send it to one or the other side.¹⁸ Figure 3 (a) plots index weights of stocks on the rank day (May 31st) in 2006. All stocks to the right of 1000th rank cutoff in May are assigned to the Russell 2000 in June. To the left of the cutoff, stocks will have smaller index weights because they are the smallest constituents of the value-weighted Russell 1000 index. Similarly, to the right of the cutoff are the largest stocks of the Russell 2000 index, so their weight is high.

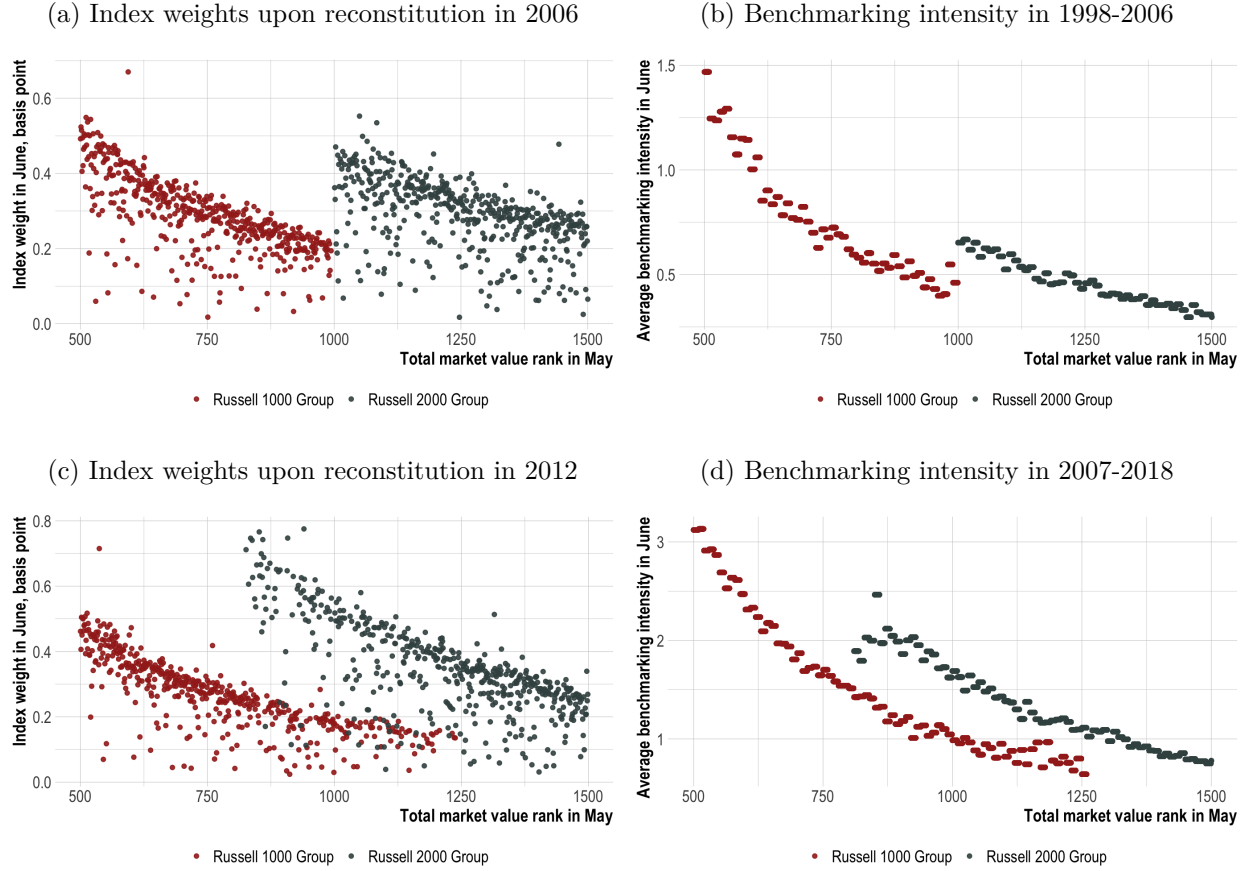

The discontinuity in index weights at the Russell cutoff drives the variation in our benchmarking intensity measure. Figure 3 (b) shows that benchmarking intensity follows this pattern because the contribution of Russell indices is large enough, even though BMI accounts for 29 benchmarks covering the cutoff.

In contrast with the literature, which typically accounts only for the Russell 1000 (blend) and Russell 2000 (blend), we consider all nine Russell indices on both sides of the cutoff. These indices include the Russell 1000 (blend, value, and growth) and Russell Midcap (blend, value, and growth) to the left of the cutoff and the Russell 2000 (blend, value, and growth) to the right of it.¹⁹ Style funds (i.e., value and growth) have historically had a larger market share on the Russell 1000 side of the cutoff, while blend funds have been more

¹⁸Extensive details on the Russell reconstitution are reported in Section A.9 of the Appendix. Introduction of the ‘banding’ policy is discussed therein.

¹⁹This set does not include Russell indices that do not exhibit discontinuity in weights near the 1000/2000 cutoff. These are, for example, Russell 3000, Russell 2500, and Russell Small Cap Completeness. However, all these indexes are still in the BMI, they just do not contribute to the discontinuity.

Figure 3: Discontinuities in Index Weights and BMI before and after 2006

This figure plots index weights and benchmarking intensity against the total market value rank on the rank day in May. Index weights are a snapshot on the reconstitution date in 2006 (June 30th) and 2012 (June 29th). Benchmarking intensity is averaged for constituents of each index across bins of 10 stocks and over the relevant period. Russell 1000 Group includes the Russell 1000 and Russell Midcap (blend, value, and growth). Russell 2000 Group includes the Russell 2000 (blend, value, and growth).

important on the Russell 2000 side. Moreover, we include funds benchmarked to the Russell Midcap – an index which spans stocks smaller than rank 200 within the Russell 1000. It assigns a higher weight to the stocks near the cutoff than the Russell 1000 index because it excludes its 200 largest constituents. The market share of funds benchmarked to the Russell Midcap in our sample is almost as high as that of all Russell 2000 funds (Figure 5 and Table 16 in the Appendix).

Due to the updated reconstitution methodology, since 2007 there is a market value region in which both Russell 1000 and Russell 2000 stocks are present. Figure 3 (c) plots the index weights around the cutoffs on the rank day (May 31st) in 2012. In that year, the band is between ranks 823 and 1243. The discontinuity is still apparent: Russell 2000 stocks

(in grey) have higher index weights. BMI mirrors the new pattern of the weights: the plot for Russell 2000 stocks lies above that for the Russell 1000 (Figure 3 (d)).

What we exploit in most of our analysis is the higher level of BMI for stocks added to Russell 2000 or lower level of BMI for stocks just deleted from it. So we use index membership as an instrumental variable for BMI near the cutoff.

We use a local linear regression approach, i.e., our samples are restricted to the neighborhood of the cutoff (rectangular kernel). Our default bandwidth is 300 stocks around the cutoff and we report the robustness with respect to this choice in the Appendix. For the period up to 2006, the cutoff rank around which we center the analysis is 1000. For each year starting from 2007, we compute the left and right cutoffs based on the Russell methodology.²⁰

We also exclude stocks that move more than 500 ranks in one year. Our results are not sensitive to this filter but we prefer to keep it in place to ensure the comparability of stocks.

3.3.2 BMI and Index Effect

In this section, we show that a higher benchmarking intensity change leads to the larger price pressure (short-term return) upon an index inclusion event. This corresponds to Prediction 2 of our model. We first confirm that, since we use predicted index membership as an instrument for BMI, the index effect naturally follows from the existing results in the literature. Second, we present novel results suggesting that the size of the index effect is linked to the change of a stock’s BMI in the cross-section.

Similarly to Chang et al. (2014), we see a positive return upon addition to the Russell 2000 and a negative return following a deletion from it in our data. Identification details and estimation results are presented in Table 10 in the Appendix. This result corresponds to the findings of Chang et al. because we use the change in BMI predicted by index membership change.²¹ Moreover, our price pressure estimates based on index dummy instead of ΔBMI lie within the ranges documented in the Internet Appendix to their paper (see Table 11 in the Appendix).

Next, we show that the larger the stock’s change in BMI, the higher its return in June. We deflate BMI because otherwise the actual June index weights will include the (post-announcement) price pressure and mechanically exhibit a positive relationship with

²⁰Market value levels for the cutoffs we compute are reported in Table 6 in the Appendix, we almost fully match historical values reported by Russell on the website: <https://www.ftserussell.com/research-insights/russell-reconstitution/market-capitalization-ranges>.

²¹As expected, BMI change is also well-instrumented by index membership change. See the first-stage details in Table 10.

June returns. Specifically, deflated BMI is computed using index AUM shares in June but weights as of May; that is, it accounts for the new index membership of stock i but not its return in June.²² Therefore, we estimate the following specification:

$$Ret_{it}^{June} = c_t + \alpha \Delta BMI_{it} + \beta \log MV_{it} + \delta' \bar{X}_{it} + \varepsilon_{it} \quad (5)$$

In this specification, Ret_{it}^{June} is the return of stock i in June of year t ,²³ winsorized at 1%. ΔBMI_{it} is the difference between the BMI of stock i in May of year t and its deflated BMI in June of the same year. c_t is a year fixed effect. We also show estimation results with $\log MV_{it}$ and additional controls \bar{X} on the right-hand side, the role of which will become clear later, from Section 4 onwards.²⁴ $\log MV_{it}$ is the logarithm of total market value, the ranking variable as of May provided by Russell. Conditional on $\log MV$, most of the variation in the change in stock BMI from May to June is defined by the Russell reconstitution.²⁵ The results are not sensitive to these controls. We perform this estimation for all stocks within 300 ranks around rank 1000.

Estimation results are presented in Table 2. Consistent with our model’s Prediction 2, price pressure is the highest for stocks experiencing the largest increase in BMI, all else equal. Similarly, stocks experiencing the largest drop in BMI also have the most negative return in June. To better understand the magnitudes, we report the estimates of price pressure in quartiles of BMI change. A stock in the top quartile has a 80bps higher return in June relative to an average stock in that year, while a stock in the bottom quartile has a 110bps lower return. These magnitudes are consistent with the index effect size we get with a standard approach. The results are robust to alternative specifications.²⁶

Therefore, in contrast with the existing literature which looks at the average index effect for stocks added to the index or deleted from it, our analysis suggests that the size of index effect is proportional to the stock’s BMI change.²⁷ It is a natural result because, as

²²Results are robust to alternative, shorter, deflators and to using AUM shares as of May or March.

²³Consistent with [Chang et al. \(2014\)](#), June is the month when we expect the price pressure due to the Russell reconstitution.

²⁴Specifically, we add the following controls. \bar{X} is a vector consisting of: 5-year monthly rolling β^{CAPM} computed using CRSP total market value-weighted index, Russell float factor (proprietary liquidity measure affecting index weight), 1-year monthly rolling average Bid-Ask percentage spread, and stock return over year $t - 1$.

²⁵We show in Table 12 in the Appendix that this specification is robust to controlling for previous index membership, being in the Russell band, and their interaction. Membership in CRSP indices is mostly defined by the total market value as well. We confirm robustness to including CRSP banding controls in unreported tests.

²⁶Estimates for a specification with narrower bands and with fewer controls are presented in Table 13 in the Appendix. In unreported analysis, we ran the regression with terciles and quintiles of BMI change instead of quartiles and the results are similar.

²⁷[Greenwood \(2005\)](#) and [Wurgler and Zhuravskaya \(2002\)](#) perform a cross-sectional analysis for one bench-

we show in the following section, the change in BMI, in fact, allows us to compute the price elasticity of demand.

Table 2: Deflated BMI change and return in June

	Return in June						ΔBMI , %
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
ΔBMI	0.148*** (7.03)	0.147*** (6.58)	0.147** (2.65)				
ΔBMI quartile 1				-0.013*** (-7.99)	-0.011*** (-6.67)	-0.011*** (-3.75)	-18.5
ΔBMI quartile 2				-0.007*** (-4.23)	-0.004** (-2.52)	-0.004* (-1.79)	-2.2
ΔBMI quartile 3				0.007*** (4.16)	0.004** (2.28)	0.004** (2.37)	6.6
ΔBMI quartile 4				0.013*** (6.28)	0.008*** (3.89)	0.008*** (2.80)	44.9
Controls	N	Y	Y	N	Y	Y	
Fixed effect	Year	Year	Year	NA	NA	NA	
Clusters	Stock	Stock	Stock & Year	Stock	Stock	Stock & Year	
Observations	11,941	10,843	10,843	11,941	10,843	10,843	
R^2 , %	0.57	13.23	13.23	1.16	13.35	13.35	

This table reports the results of specification (5) for stocks in the full sample (1998-2018). The dependent variable is the winsorized return of stock i in June in year t (in columns (1)-(3) and demeaned by year in (4)-(6)). The independent variable is ΔBMI_{it} , the change in the BMI of stock i between June and May of year t deflated to May prices, or the dummies for its quartiles. Controls include $\log MV$, the ranking variable, and other controls \bar{X} , demeaned by year in columns (4)-(6). Band width is 300 around rank 1000. The last column reports the mean percentage ΔBMI_{it} in each quartile. t-statistics based on clustered standard errors are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

3.3.3 Implications for the Price Elasticity of Demand

Our heterogeneous benchmarks model has nontrivial implications for the stock price elasticity of demand. Even though this parameter is of key importance for numerous macroeconomic models, the literature offers a rather wide range of its estimates (e.g., [Wurgler and Zhuravskaya \(2002\)](#)) and sometimes focuses on the demand curves of different groups of investors. Importantly, previous research has studied single stock demand curves using only one benchmark (starting from [Shleifer \(1986\)](#)) and, in most cases, assumed that only passive managers (index funds and ETFs) have inelastic demand.

For the experiment below, consider a one-stock version of our model ($N = 1$). Addi-

mark and show that arbitrage risk is positively associated with the index effect of Nikkei 225 and S&P 500 stocks, respectively.

tionally, to fix ideas, we separate fund managers into active and passive ones, as in footnote 11.

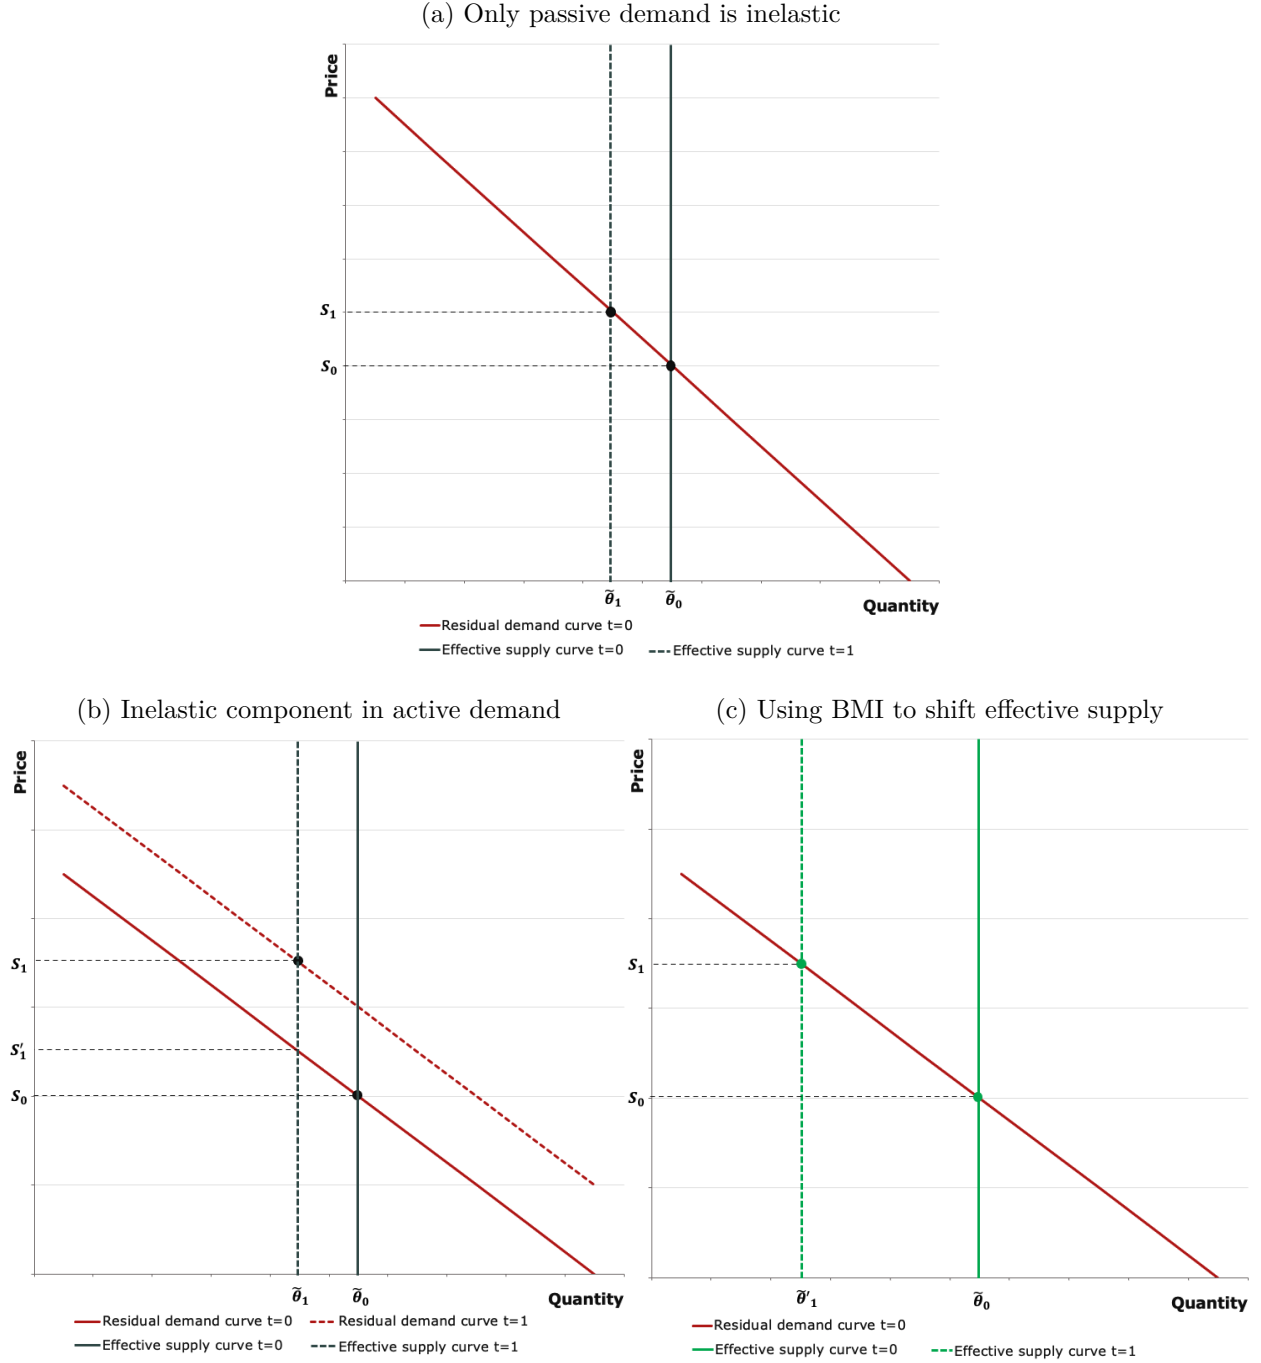

Most of the existing literature implicitly assumes that active investor demand (corresponding to benchmarked active managers and direct investors in our model) is fully elastic. If it is the case, the change in passive investor demand due to index reconstitution can be used as a shock to the supply of shares available to the rest of the market (effective supply). This is illustrated in Figure 4 (a). When the passive investor demand increases, the effective supply reduces from $\tilde{\theta}_0$ to $\tilde{\theta}_1$, and the new equilibrium price is higher, $S_1 > S_0$. Using the change in passive benchmarked assets that corresponds to $\tilde{\theta}_1 - \tilde{\theta}_0$ and the size of the index effect, i.e., $(S_1 - S_0)/S_0$, allows us to measure the price elasticity of demand of the rest of the market, typically computed as $(\tilde{\theta}_1 - \tilde{\theta}_0)/(S_1 - S_0) \times S_0/\tilde{\theta}_0$. We refer to the demand of the rest of the market as residual demand.

In our model, however, the standard approach will not recover the price elasticity of demand. The demand of passive managers benchmarked to index j for any particular stock is fully inelastic: $\theta_j^P = \omega_j$. Then, the effective supply of shares available to benchmarked active managers and direct investors is $\tilde{\theta} = \bar{\theta} - \sum_j \lambda_j^P \omega_j$. Due to benchmarking, the aggregate demand function of benchmarked active managers and direct investors features an inelastic component, the last term in the equation below.

$$\Theta^{Active+Direct} = \frac{1}{\gamma} A^{-1} \Sigma^{-1} (\bar{D} - S) + \frac{b}{a+b} \sum_j \lambda_j^A \omega_j$$

This equation as a function of S represents the demand curve in Figure 4 (b). With benchmarking, an index inclusion event will not only trigger a parallel shift in effective supply to the right but also an upward parallel shift in residual demand. As illustrated in Figure 4 (b), the observed price pressure will be $(S_1 - S_0)/S_0$, not $(S'_1 - S_0)/S_0$. If we use the latter price pressure with the change in passive demand to compute elasticities, we will conclude that the residual demand curve is steeper than it actually is. Therefore, if the world is close to our model economy, using the benchmarked passive asset change and the observed price pressure does not deliver the correct estimate of the price elasticity of demand. As shown in Section 4, active managers indeed have inelastic demand for stocks in their benchmarks and constitute, on average, 80% of asset managers in our sample.

Figure 4: Demand Curves and Index Effect

This figure illustrates index reconstitution implications when (a) only passive investors' demand reacts inelastically, (b) active investors also have inelastic component in demand function, and (c) when BMI change is used to shift effective supply. Effective supply in (a) and (b) is the total supply of shares, $\bar{\theta}$, minus the holdings of passive managers. In (c), it additionally excludes the inelastic component of holdings of active managers. Residual demand is the total demand of the rest of the market, i.e., (elastic) active managers and direct investors.

What is the appropriate way to compute elasticity? One could separate elastic and inelastic components of active managers' demand and subtract the latter from the effective supply: $\tilde{\theta}' = \bar{\theta} - \left[\sum_j \lambda_j^P \omega_j + \frac{b}{a+b} \sum_j \lambda_j^A \omega_j \right]$. But in the data, we normally do not observe these components individually. In our model, however, BMI is exactly $\sum_{j=1}^J \left[\lambda_j^P \omega_j + \frac{b}{a+b} \lambda_j^A \omega_j \right]$. In other words, the change in BMI due to an index reconstitution event directly measures the shift in effective supply resulting from the inelastic response of both passive and active managers.²⁸ This is illustrated in Figure 4 (c). The difference between the solid grey and dashed green lines is the total change of effective supply due to inelastic demand of both active and passive managers. Since this change in BMI is observable, it allows us to trace the correct slope of the residual (elastic) demand function.

Using an appropriate scaling for the deflated change in BMI and the average index effect of 2.3%, we get the average price elasticity of demand of -3.03 in 1998-2018.²⁹ Table 14 in the Appendix reports sensitivity of our estimate to the index effect size. The corresponding values of demand change per year are shown in Table 15 in the Appendix. Therefore, our model implies flatter demand curves than in a standard approach that posits that all active demand is elastic.³⁰

Importantly, the heterogeneity of benchmarks has significant quantitative implications for the measures of elasticity relative to a single-benchmark case. Appendix A.19 shows that the BMI change is proportional to the change in total benchmarked assets used by Chang et al. (2014) only if a stock does not enter any benchmark other than the Russell 1000 and 2000. The literature has not considered the demand that stems from such large indices as the Russell 1000 Growth and Russell Midcap,³¹ and hence the change in

²⁸Data on manager compensation are generally not available. The only estimate of $\frac{b}{a+b}$ in the literature is provided in Ibert et al. (2017) on Swedish data, which exhibits structural differences to the US. We assume that $\frac{b}{a+b} = 1$ in our main results but also provide a sensitivity analysis to this ratio.

²⁹To infer a percentage demand shock, we need to multiply the change in BMI by the total equity market cap and divide by the average stock market value around the cutoff. See Appendix A.19 for a detailed explanation.

³⁰Our main calculation of demand elasticities is based on $\frac{b}{a+b} = 1$, which implies that active managers are strongly concerned about relative performance and the sensitivity of their compensation to absolute performance, a , is small. If a is higher, the inelastic component constitutes a smaller fraction of their demand for risky stocks. Therefore, they contribute less to the overall inelastic demand in the economy. In the language used in this section, it means that the shift in effective supply of a stock due to an index inclusion is smaller. In our calculation, the corresponding change in the stock's price is fixed, as estimated in the data. Hence, the same change in price is associated with a smaller change in demand, resulting in lower elasticity of residual (elastic) demand. For example, for $\frac{b}{a+b} = 0.5$ and $\frac{b}{a+b} = 0.8$, the price elasticity of the residual demand would be -1.72 and -2.51, respectively. If the shift in the dashed green line in Figure 4 (c) is smaller, the residual demand curve (red line) must be steeper to result in the same (observed) price change.

³¹Benchmarked assets of the Russell indices are shown in Table 16. Russell Value and Growth indices are even larger than blend indexes in terms of the assets benchmarked to them. Moreover, since the Russell Midcap represents the smallest 800 stocks in the Russell 1000, the stock would exit it too. The size of the

demand is typically mismeasured. As shown in Table 14 in the Appendix, accounting for all benchmarks in the same sample and with the price pressure estimate as in Chang et al., we obtain elasticity of -1.11 (24% less elastic than -1.46 in their paper). Overall, by taking into account stock weight changes in all 33 indices and their historical market shares, our measure provides a more accurate estimate of the price elasticity of demand.

Discussion in this section mostly concerns the index effect literature. Recent papers using the demand system approach to asset pricing (proposed in Kojen and Yogo (2019)) are not subject to the criticism above as they estimate elasticities at an investor group level. They find that institutions have less elastic demand than most theories would predict. Our paper suggests a mechanism for their finding and a way to quantify it using BMI.

In the following section, we discuss the existing evidence of inelastic demand of active benchmarked managers and provide new results on our granular benchmark data.

4 Benchmarking Intensity and Institutional Ownership

Starting from Gompers and Metrick (2001), empirical literature documented a range of effects of institutional trading and ownership for stock prices. A recent strand of literature looks into the effects of ownership on corporate outcomes. There has been little research, however, on the benchmarking-induced ownership.

Benchmarking intensity reflects the incentives elicited by the contracts of asset managers, both active and passive. In this section, we show that both investor types have a considerable fraction of holdings concentrated in their benchmarks and that they rebalance stocks relevant for *their* benchmarks around the Russell cutoffs. That is, we document a heterogeneity of investor habitats dictated by their benchmarks, reflecting their inelastic demand for stocks in these benchmarks.

4.1 Benchmarks as Funds' Habitat

As Robert Stambaugh points out in his AFA Presidential Address (Stambaugh (2014)), U.S. mutual funds' tracking errors have been going down. In our dataset, this trend is drastic. A simple average tracking error of active funds went down from 7% per annum in the early 2000s to below 4% in 2010s. For passive funds, these numbers have been below 2% and closer to 0.5%, respectively. Given that the share of passive funds grew significantly over the

investor base of the Russell Midcap is just as large as that for the Russell 2000. It is therefore surprising that most of the literature studying the Russell cutoff has not taken all these indices into account.

past two decades,³² the overall industry tracking error is at its historical low.³³

Exploiting the granularity of our dataset, we also compute the percentage of fund AUM invested in its benchmark stocks and the number of benchmark stocks held. Over our sample period (1998-2018), the AUM share in the benchmark stocks has risen from 75% to 82% for active funds. The number of benchmark stocks they hold has also risen from 60% to 80% of the total number of stocks in their portfolios. Both figures have consistently been close to 100% for passive funds.

These trends suggest that benchmarks define funds' preferred habitats.³⁴ In the following section, we document that funds actually rebalance stocks added to or deleted from their benchmarks.

4.2 Net Purchases of Index Additions and Deletions

Earlier studies documented that Russell index funds and ETFs buy additions to and sell deletions from their benchmarks. We argue that this list is incomplete and that active managers engage in the same behavior but detecting it requires granular data on their benchmarks.

In order to see which funds rebalance additions and deletions, we estimate the following specification at a stock level:

$$\Delta Own_{ijt} = c_j + \gamma_j D_{it}^{Index} + \beta_j \log MV_{it} + \delta'_j \bar{X}_{it} + \epsilon_{ijt} \quad (6)$$

In the above specification, D_{it}^{Index} is 1 when stock i is in the respective index, the Russell 1000 or Russell 2000, on the reconstitution day in June of year t . ΔOwn_{ijt} is the change in the fraction of shares outstanding of stock i owned by fund group j from March to September of year t . The funds are grouped by benchmark and type (active/passive), e.g., active funds benchmarked to the Russell 1000 index. Because changes in the ownership share are more difficult to detect for fund groups with smaller AUM, we also report the results for extensive margin, with the trade dummy used as a dependent variable. We perform analysis on September holdings data because: (1) it allows for delayed rebalancing

³²The assets of stock index mutual funds and ETFs now match that of active funds, according to: <https://www.bloomberg.com/news/articles/2019-09-11/passive-u-s-equity-funds-eclipse-active-in-epic-industry-shift>.

³³Another prominent measure of fund activeness is active share, proposed by Cremers and Petajisto (2009). Funds' active share is also decreasing over time in our sample.

³⁴All our analysis is conditional on the benchmark in the manager's contract. Our model does not take a stand on how end investors pick the benchmark or fund to invest in. Possible rational explanations include the need to hedge endowment shocks of a particular type or to hedge displacement risk. Behavioral explanations include psychological foundations for why investors prefer growth over value, over-reaction, and extrapolation of past returns.

after June reconstitution³⁵, (2) it is based on quarterly holdings³⁶, and (3) it is in line with most of the previous studies (e.g., Appel et al. (2016)). $\log MV$ is the logarithm of total market value, the ranking variable as of the rank day in May provided by Russell. c_j is a group-specific constant. \bar{X} is a vector of other controls, all as of the end of May: 5-year monthly rolling β^{CAPM} computed using CRSP total market value-weighted index, Russell float factor (proprietary liquidity measure affecting index weight), 1-year monthly rolling average Bid-Ask percentage spread, and stock return over year $t - 1$.³⁷

Conditional on $\log MV$, dummy D_{it}^{Index} represents an exogenous change in index membership. We confirmed that the results are equivalent to using a 2SLS estimator, with index membership instrumented with a prediction as of the rank date in May. Hence, our results identify the effect of addition to or deletion from an index without a concern that an omitted variable might be driving both membership in the index and the change in ownership of funds benchmarked to that index.

We estimate specification 6 on additions and deletions separately, at an index level, and distinguish between active and passive funds benchmarked to that index. For example, we run a separate regression for the change in the ownership share of the active Russell 1000 funds in stocks that were in the Russell 1000 on the rank day in May. In this example, the interpretation of γ on D^{R2000} is the change in their ownership share due to the stock's addition to the Russell 2000 index (and its deletion from the Russell 1000 index group – i.e., the Russell 1000 blend, Russell Midcap blend, and their value and growth counterparts.).³⁸

Table 3 documents that both passive and active funds rebalance additions and deletions. We report the most conservative results with double-clustered standard errors. Consistent with the literature, we find highly significant stock ownership changes for passive funds in line with their benchmarks. For example, passive funds benchmarked to the Russell 2000 purchase 112bps of shares of stocks added to the Russell 2000 compared to stocks that stayed in the Russell 1000. These funds also sell deleted stocks in similar proportions (91bps). At the same time, we see that active funds benchmarked to the Russell 2000 also sell deletions, decreasing their ownership share by 46bps. Another example is that active funds benchmarked to the Russell MidCap sell, on average, 29bps of deleted shares (from Russell 1000 and Midcap) and buy 20bps of the added ones.

³⁵In undocumented analysis, we see that after 2007 a considerable fraction of rebalancing of additions and deletions happens in July.

³⁶These holding records are more complete because their filing is mandatory on a quarterly basis for most of our sample.

³⁷We discuss in Section 5.4.5 that these controls are useful to ensure that the control group is truly comparable. Our specification does not include year and industry fixed effects because of insufficient variation within additions and deletions samples. Results are qualitatively similar if we include them.

³⁸We explore even more granular rebalancing by style in Section A.24 in the Appendix.

Table 3: Rebalancing of additions and deletions, by benchmark and fund type

Summary of separate regressions on additions and deletions						
Change in the ownership by investor group						
Benchmark Fund type	Stocks ranked < 1000				Stocks ranked > 1000	
	Russell 1000		Russell Midcap		Russell 2000	
	Active	Passive	Active	Passive	Active	Passive

This table reports γ_j from estimating (6) in the full sample period (1998-2018). Estimation is performed at group j level (by benchmark and fund type). The coefficients come from separate regressions: on stocks that were in the Russell 1000 (so that D^{R2000} indicates addition to the Russell 2000) or in the Russell 2000 (D^{R1000} indicates deletion) in the previous year. Band width is 300 stocks around the respective cutoff. The dependent variable in panel A is the change in fraction of shares owned by the respective investor group of stock i from March to September in year t . In panel B, it is the direction of the trade of the group (1 for buy, 0 for no trade, and -1 – for sell). In panel C, it is the ownership share in September. In panel D, it is a dummy that equals 1 if the stock is held by the group and 0 if it is not. Regressions in both panel C and D additionally control for the dependent variable in March. All regressions include log total market value ($\log MV$) and all other controls in \bar{X} . In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

On the extensive margin, the benchmark-driven rebalancing is even easier to detect. As Panel B of Table 3 reveals, active funds are likely to sell deletions from their benchmarks and buy additions relative to a set of comparable stocks that did not switch indices. Panel D shows that all fund groups in our sample are more likely to hold stocks added to their benchmarks and less likely to hold the deleted stocks.

Our results are robust to alternative specifications, varying band widths and control-

ling for the polynomials of the ranking variable, $\log MV$.³⁹ In Table 21 in the Appendix, we use the approach of Appel et al. (2019a) on our data. One cannot detect a discontinuity in the *total* ownership of active mutual funds. However, the discontinuities are apparent when active funds are split by the benchmark.⁴⁰ These results speak to the importance of mandates for both active and passive funds.

Because the composition of active funds holding the added stock changes significantly, the incentives to monitor this stock may change too. This may affect corporate governance, casting doubt on the plausibility of the exclusion restriction in the growing number of studies on the Russell cutoff.⁴¹

Overall, the results in this section suggest that, in line with our theory, benchmarks serve as both active and passive funds' preferred habitats. However, they reveal the total effect of index reconstitution on ownership. That is, the coefficients reported in Table 3 include both elastic and inelastic response to the change in index membership. In the following section, we empirically separate the two using BMI.

4.3 Evidence for Benchmarking-Induced Inelastic Demand

In this section, we show that the rebalancing we document above is driven by inelastic demand. We have shown that active funds trade index switchers in the direction imposed by their benchmarks. For funds to the left of the Russell cutoff, i.e., Russell 1000 and Midcap funds, this direction is the same as the elastic response to the index price pressure. For example, if a stock is added to the Russell 2000, its price increases. If demand curves are price-elastic, any fund is expected to sell the stock because it became more expensive. Therefore, an active fund benchmarked to the Russell 1000 selling this stock might do so not because of benchmarking but because its demand is elastic.

In the language of our model, it is easy to see that BMI allows to separate two types of demand. If a stock moves from index 1 to index 2, the corresponding element in ω_1 changes from a positive value to 0, and the corresponding element of ω_2 changes from 0 to a positive value. The other elements remain the same. Considering the mass of the respective fund managers, the stock's total BMI change is $\Delta BMI = \lambda_2 \omega_2 - \lambda_1 \omega_1$. The change in demand

³⁹We report the results for a wider band in Table 17 in the Appendix. Furthermore, Table 18 in the Appendix reports the estimates in subsamples. Table 19 in Appendix includes year fixed effects.

⁴⁰Our findings do not contradict Appel et al.: because of the sheer size of the Russell 2000 passive funds, the total passive ownership is higher for stocks to the right of the cutoff.

⁴¹The list of papers includes but is not limited to: Appel et al. (2019b), Glossner (2018), Heath et al. (2018), Schmidt and Fahlenbrach (2017), Appel et al. (2016).

of all fund managers benchmarked against index 2 is (from (2)):

$$\lambda_2 \Delta \theta_2 = \frac{\lambda_2}{\gamma(a+b)} \Sigma^{-1} (S_1 - S_2) + \frac{b}{a+b} \lambda_2 \omega_2$$

Using the price from (3) to express the index effect ($S_1 - S_2$) in BMI terms, it is easy to show that:

$$\lambda_2 \Delta \theta_2 = -A \frac{\lambda_2}{(a+b)} \Delta BMI + \frac{b}{a+b} \underbrace{\lambda_2 \omega_2}_{\Delta \text{bmi}_2}$$

This equation incorporates the equilibrium price response to a change in index membership. The first term represents the elastic response to the corresponding change in price. If the total change in BMI is positive, index price pressure is positive, requiring the managers to sell (movement along the demand curve). The second term is the inelastic response due to benchmarking. It depends on the manager-level change in BMI, denoted Δbmi_2 for manager with benchmark index 2. Because all quantities are observable, we can bring this to the data.⁴²

We estimate the following specification at a stock level which attempts to separate elastic and inelastic demand components in the data:

$$\Delta \text{Own}_{ijt} = c_{jt} + \alpha_j \Delta BMI_{it} + \gamma_j \Delta \text{bmi}_{ijt} + \beta_j \log MV_{it} + \delta'_j \bar{X}_{it} + \epsilon_{ijt} \quad (7)$$

ΔOwn_{ijt} is the change in fraction of shares of stock i held by group j from March to September of year t . The funds are grouped by benchmark and type (active/passive). ΔBMI_{it} is the change in the total BMI of stock i , with $\Delta BMI_{it} = \sum_j \text{bmi}_{ijt}$. Δbmi_{ijt} is the change of BMI of stock i attributable to the benchmark and assets of group j , e.g., active funds benchmarked to the Russell 1000 index. We deflate both as in the earlier analysis to avoid the mechanical relationship with the return in June. The rest of the specification is as in the earlier analysis too. Because we are using changes in BMI, we estimate this regression for additions and deletions jointly.

The total change in stock BMI, ΔBMI , serves as a theoretically motivated proxy for the change in stock price upon index membership change.⁴³ In Section 3.3.2, we showed that the index effect is proportional to ΔBMI in the cross-section. We also use the quartile of ΔBMI as an alternative proxy as it has less noise.

⁴²In the data, vectors ω typically change for several classes of managers simultaneously, e.g., those benchmarked to the Russell 1000 and Russell Midcap, and their value and growth counterparts.

⁴³In this test, the inelastic demand components of passive and active managers contribute to BMI with the same weight. In our theory, however, the weight on the active managers' inelastic demand is $\frac{b}{a+b}$. We do not have a measure for it so we experimented with several choices of $\frac{b}{a+b}$ when constructing BMI for this regression. The results remained qualitatively the same.

Results reported in Table 4 suggest that the rebalancing of active funds is due to the inelastic component in managers' demand. Coefficient on Δbmi_j is positive and significant for all indices. The coefficient on ΔBMI has the expected sign in most cases. The regressions on passive funds indicate that they are fully inelastic investors, as expected. The results are robust to reducing the band width as shown in Table 22 in the Appendix.

Table 4: Elastic and inelastic components of change in ownership

Change in percentage of firm's common shares held by						
	Active funds benchmarked to:			Passive funds benchmarked to:		
	Russell 1000	Russell Midcap	Russell 2000	Russell 1000	Russell Midcap	Russell 2000
Panel A: Using ΔBMI						
ΔBMI	-0.004 (-1.39)	-0.009* (-2.00)	-0.015* (-1.88)	0.000 (0.69)	-0.000 (-0.17)	-0.007 (-1.32)
Δbmi_j	0.013 (1.37)	0.032** (2.46)	0.030*** (4.11)	0.472*** (12.25)	0.641*** (19.97)	0.614*** (18.29)

Panel B: Using ΔBMI quartile						
ΔBMI quartile	0.000 (1.06)	-0.000 (-0.74)	-0.000 (-1.52)	-0.000 (-0.31)	-0.000 (-1.72)	0.000 (0.91)
Δbmi_j	0.020** (2.34)	0.040*** (3.36)	0.023*** (5.64)	0.462*** (11.88)	0.639*** (15.83)	0.566*** (13.35)
Observations	10,843	10,843	10,843	10,843	10,843	10,843
Within R^2 , %	0.6	1.8	1.5	36.3	55.5	50.2

This table reports the estimates of (7) in the full sample (1998-2018). The dependent variable is the change in fraction of shares owned by the respective investor group of stock i from March to September in year t . Panel A reports the results with ΔBMI used to capture the elastic response, and panel B - ΔBMI quartile. Δbmi_j is the change in BMI attributable to group of funds j , e.g., active Russell 1000 funds. All regressions include year fixed effects, log total market value ($\log MV$), and other controls \bar{X} . Band width is 300 around rank 1000. In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

We also see that splitting active funds by their median tracking error⁴⁴ produces results in line with the theory. As Table 23 in the Appendix reports, funds with lower tracking errors rebalance in line with the predicted inelastic demand while funds with higher tracking errors do not do so. In our model, these higher tracking error funds would have weaker relative performance incentives, implying that b is close to zero, so the inelastic component in their demand would be very small.

⁴⁴Tracking error is a standard deviation of the daily difference between the return of the fund and the return of its benchmark.

In sum, BMI helps us attribute the rebalancing of active funds to an inelastic component in their demand function, as predicted by our theory.

5 Benchmarking Intensity and Stock Risk Premium

5.1 Identification Approach

Our goal in this section is to test the negative relationship between benchmarking intensity and stock returns predicted by our theory. For that, we need exogenous variation in BMI and the Russell cutoff provides a convenient setup.⁴⁵ Given the random assignment of stocks around the cutoff on the rank day in May, index membership in June is a valid instrument for BMI. Stocks in the neighborhood of the cutoff share similar properties as an idiosyncratic market value shock on the rank day can put them to one or the other side of the cutoff.

We use an instrumental variable strategy to identify the effect of BMI on long-run returns. Specifically, we use inclusion in the Russell 2000 in June as an instrument for BMI in September.⁴⁶ We control for end-of-May stock market capitalization because it affects BMI for reasons other than index assignment.⁴⁷ We use the following stock-level two-stage specification to estimate γ_1 :

$$BMI_{it} = c_0 + \gamma_0 D_{it}^{R2000} + \beta_0 \log MV_{it} + \delta'_0 \bar{X}_{it} + \varepsilon_{1it} \quad (8)$$

$$Y_{it+h} = c_1 + \gamma_1 \widehat{BMI}_{it} + \beta_1 \log MV_{it} + \delta'_1 \bar{X}_{it} + \varepsilon_{2it} \quad (9)$$

In the above specification, D^{R2000} is 1 when stock i is in the Russell 2000 on the reconstitution day in June of year t . Y_{it+h} is an average long-run return of stock i from September of year t over the investment horizon h . Specifically, we consider the 12-, 24-, 36-, 48-, and 60-month excess returns, which are not risk-adjusted. We also consider periodic returns, i.e., the average returns of 1-12, 13-24, 25-36, 37-48, and 49-60 months. \widehat{BMI}_{it} is the predicted BMI value from the preceding stage, (8). We use BMI_{it} calculated as of September.⁴⁸ $\log MV$ is

⁴⁵Our identification is built around the change in stock weight in the benchmark. An alternative avenue would be to use a shock to the AUM share of the benchmark (see BMI definition in Section 3.2). Finding such a shock is a non-trivial task, especially because we need to keep the total share of managers constant. Otherwise, according to our model, a change in λ_j would affect the market's effective risk aversion via A (see equation (3)).

⁴⁶In unreported analysis, we compare our results to that of a 3SLS procedure, which includes the prediction step for the index dummy. The results are almost identical.

⁴⁷Importantly, this market capitalization measure comes directly from Russell and almost precisely defines index membership, which assures that the results are close to the analogous 3SLS.

⁴⁸The reason is that we want to avoid sorting on the initial price pressure that occurs mostly in June as

the logarithm of total market value, i.e., the ranking variable as of May provided by Russell.⁴⁹ \bar{X} is a vector of other controls that include: 5-year monthly rolling β^{CAPM} computed using the CRSP total market value-weighted index, Russell float factor (proprietary liquidity measure affecting index weight), 1-year monthly rolling average bid-ask percentage spread, and stock return over year $t - 1$.⁵⁰

We perform estimation separately for additions and deletions. That is, we first estimate specifications (8)-(9) only for stocks that belonged to the Russell 1000 in the previous year. In this case, D^{R2000} distinguishes stocks that got added to the Russell 2000 (treated) from stocks that stayed in the Russell 1000 (control). Similarly, we run the test for the sample of Russell 2000 stocks only and compare stocks that stayed in the Russell 2000 (treated) with stocks that got moved to the Russell 1000 (control). This is consistent with Chang et al. (2014).

Our dependent variable spans horizons from 12 months to 5 years. There is some ambiguity about what the long run is in the literature. The IPO performance literature (following Ritter (1991)) typically defines it as three years. The long-run reversal literature (started by De Bondt and Thaler (1985)) uses horizons from 18 months to five years. In our case, an additional problem is posed by flippers, i.e., stocks that switch from one benchmark to the other during the horizon that we are considering. Our model requires the stock's BMI to remain largely unchanged for the expected return result to play out as predicted. We comment on flippers further in Section 5.4.4.

Our samples are restricted to 300 stocks around the cutoff. We also report the main estimation results with the bandwidth of 100 in Table 29 in the Appendix.

5.2 BMI and Long-Run Returns

In this section, we show that a higher benchmarking intensity leads to lower returns in the long run. Specifically, we use \widehat{BMI}_{it} , the benchmarking intensity instrumented with stock index membership, to show that stocks with a higher intensity in year t significantly underperform up to year $t + 5$.

discussed in later sections.

⁴⁹The main specification will only include $\log MV$ but following the practice in the literature, we confirm robustness to polynomials of $\log MV$ up to order 3 in unreported tests.

⁵⁰We report results with and without covariates for consistency with the model. Our theoretical prediction for the expected return (4) highlights that stocks may have different fundamental exposure through β_i – so we add β^{CAPM} . We include the float factor and bid-ask spread to address the liquidity hypothesis for index effect. Past return is included because we see that it is imbalanced for the treated and control samples in the covariate tests, currently unreported, and it may affect long-run returns through momentum. We leave out book-to-market ratio, which does not change our results quantitatively or qualitatively. We document covariate-free estimation results for the reduced form specification in the Appendix.

Index membership is a valid instrument for benchmarking intensity. We report the results of the second stage regression of the benchmarking intensity on Russell 2000 membership and controls in Section A.10 in the Appendix. As was previously mentioned, we could also use predicted index membership instead. Index membership is well-instrumented by the assignment prediction dummy τ . Table 9 in the Appendix explicitly documents these estimation results.

Results of estimating the second stage regression in the full sample period are documented in Table 5. As the coefficient on BMI is significantly negative, stocks with higher benchmarking intensities have lower returns in the future. The effect persists for up to 5 years into the future for additions to the Russell 2000 and 2 years for deletions from it.⁵¹

The magnitude of this effect is economically significant. In order to interpret the magnitude for an average added or deleted stock in our sample, we need to take into account the first stage coefficient or refer to the reduced form regressions. The reduced form regression results are included in Tables 25 and 26 in the Appendix. In the 1998-2006 sample period, addition to the Russell 2000 results in around 60bps lower return per month in the next five years⁵² while deletion from it leads to a 48bps higher return per month. After 2007, the magnitudes decrease: addition to the Russell 2000 results in around 26bps lower return while deletion leads to a 28bps higher return.⁵³

Consistent with the model, this analysis shows that an increase in the size of the preferred habitat has a long-lasting⁵⁴ effect on stock returns. This result can also be interpreted as a negative long-term return of a long-short portfolio that buys stocks with high BMIs and sells stocks with low BMIs.⁵⁵ In other words, inelastic demand from the benchmarked institutions does indeed lower the stock risk premium.

⁵¹Even though it might seem from Panel A that most of the effect is concentrated in the first 12 months after index reconstitution, the negative relationship is long-term. To confirm this, we report Panel B in Table 5, which uses average returns over a future period as the dependent variable. It shows that the returns are lowest in the 0-12 months period, and they are significantly lower for the periods between 12 and 24, 24 and 36 as well as 36 and 48 months. Second, we show in the Appendix that the effect is almost evenly negative for the full five-year horizon in the 1998-2006 sample. We explain why the introduction of banding by Russell from 2007 onwards weakens cutoffs-based tests later in this section.

⁵²According to the baseline specification. As discussed earlier, the magnitudes depend on whether we include or exclude flippers. Moreover, note that all our results are relative to the control group.

⁵³In unreported analyses, we study the magnitudes closer, allowing for heterogeneous treatment effects. We find that the size of the effect of BMI on long-run returns increases with the magnitude of BMI change. The latter corresponds to the demand shock as discussed later in the text.

⁵⁴Permanent, as long as the stock stays in the benchmark.

⁵⁵To our knowledge, while the literature has argued that the index effect lasts for over two weeks/months, no one has documented a long-run (up to 5 years) effect of index inclusion on stock returns. This is probably because this effect is hard to tease out by studying index (most commonly, the S&P 500) inclusions and using the market portfolio as a control group. In our quasi-experiment, the control group consists of stocks around the Russell cutoff, which are more similar to treated stocks.

Table 5: Benchmarking intensity and long-run returns in 1998-2018

This table reports the results of the second stage regression (9) for the full sample period. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. We limit the sample to 300 stocks around the cut-offs (rectangular kernel). The dependent variable in Panel A is an average monthly excess return from September in year t over the respective horizon. The dependent variable in Panel B is an average monthly return in the respective period, e.g., in 13-24 months after reconstitution. Panels A1 and B1 use all baseline controls while Panels A2 and B2 only include the ranking variable, $\log MV$. The baseline controls include log total market value, a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average percentage bid-ask spread, and stock return over year $t-1$. t-statistics based on HAC-robust standard errors with clusters by stock are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

It is striking that despite the predicted change in BMI being higher after 2007, the effect on returns is lower and even insignificant in some specifications (results for subsamples are reported in Table 24 in the Appendix). Before the introduction of banding, the effect is symmetric and strong for up to 5 years following index reconstitutions. After 2007, the effect for deletions is smaller in magnitude and the effect for additions lasts for 24 months only.

The weaker relationship between BMI and long-run returns in the latter part of the sample is likely to be driven by so-called optimized sampling. Optimized sampling is a portfolio construction technique in which ex ante tracking error is balanced with expected transaction costs.⁵⁶ It directly interferes with the incentives to hold the benchmark portfolio. In the presence of transaction costs, funds no longer hold benchmark securities proportionally to benchmark weights. Rather, they typically hold the largest stocks with benchmark weights, completely omit the smallest and some mid-range stocks, and overweigh most of the mid-range stocks (see the illustrations in Figures 6 and 7 in the Appendix).

With the introduction of banding in 2007, the incentives to hold stocks around the cutoffs changed. When a stock gets added to the Russell 1000 (and therefore to Russell MidCap), it has a rank of around 800, while the ranks of existing index constituents range up to 1300. This addition now contributes to funds' tracking errors significantly more than smaller stocks at the bottom of the index and it is not as expensive to trade. In other words, funds benchmarked to the Russell 1000 and Russell MidCap are now more likely to purchase this addition. At the same time, additions to the Russell 2000 obtain a rank of around 1300. Because the existing constituents now have ranks starting from 800, the contribution of these additions to funds' tracking errors is, on average, lower compared to the pre-banding period. Even though passive funds benchmarked to the Russell 2000 would still trade these stocks, active funds are less likely to do so. These different incentives correspond to a smaller change in the size of inelastic demand for additions and deletions compared to what BMI predicts and, therefore, could contribute to the performance of BMI in tests of long-run returns after 2007.⁵⁷

⁵⁶Our model abstracts from transaction costs, whereas in practice, transaction costs are an important consideration. Not buying an asset in the benchmark saves on transaction costs but increases the manager's tracking error relative to the benchmark. Optimized sampling addresses this trade-off.

⁵⁷The change of benchmarking incentives after 2007 provides an alternative explanation to the reduction in the size of the index effect over time, documented in Chang et al. (2014). The authors hypothesize that the alleviation of limits to arbitrage over time made demand curves more elastic. We provide a different explanation: the introduction of banding made funds benchmarked to the Russell 1000 and Russell MidCap participate in index rebalancing almost at par with Russell 2000 funds. For example, the stocks that are being deleted from the Russell 2000 and experiencing selling pressure from Russell 2000 funds will also experience relatively higher buying pressure from Russell 1000/MidCap funds. In other words, the price pressure from buying and selling evens out.

5.3 Implications for the Cost of Equity

Our theory predicts that higher stock BMI results in the lower cost of equity for the firm. This is a multiple-benchmark equivalent of the benchmark inclusion subsidy, proposed in [Kashyap et al. \(2020a\)](#). We use analyst estimates of the cost of equity available in Morningstar Direct⁵⁸ to test this relationship, again exploiting the Russell cutoff.

We find that firms added to the Russell 2000 have on average a 27bps lower cost of equity in the subsequent year, while firms deleted from it have a 50bps higher cost of equity.⁵⁹ The test specification is equivalent to the reduced form of the main test in Section 3.3, with the average cost of equity in the year after index reconstitution used as the dependent variable. Table 28 in the Appendix documents the estimates and shows that they are robust to accounting for the lagged cost of equity, including 3-year fixed effects, and double-clustering (magnitudes reduce to 13-25bps). The limitation of this analysis is that cost of equity estimates are not available for about a half of our sample of additions and deletions.

5.4 Robustness

5.4.1 Alternative Explanations

Recent literature has similarly exploited the Russell 1000/2000 cutoff to document a number of corporate implications of institutional ownership.⁶⁰ In this section, we explain why these findings are unlikely to explain our results.

It has been argued that transition to the Russell 2000 increases passive ownership of a stock, which may have implications for corporate governance. The positive return in June could be a signal of an improvement in corporate governance that would take place in the future. The documented effects on corporate governance, however, seem to be mixed, with some metrics improving and some deteriorating.⁶¹ Therefore, the expected cash flow or performance impact is not clear. Moreover, the majority of documented effects of Russell reconstitution on firm fundamentals are short-term: they are measured in the year following the reconstitution, while our main focus is on long-term returns.

⁵⁸Even though these estimates are by Morningstar analysts only, they cover almost 2,700 firms across 2003-2018. Moreover, the methodology used by Morningstar analysts is very similar to what the underlying companies adhere to when computing their cost of equity.

⁵⁹This effect is long-lasting. In unreported analysis, we see that the cost of equity for additions (deletions) is lower (higher) even five years after the reconstitution.

⁶⁰See the overview in [Appel et al. \(2019b\)](#). Table 31 in the Appendix lists the most common empirical approaches.

⁶¹See [Schmidt and Fahlenbrach \(2017\)](#), [Appel et al. \(2016\)](#) and [Crane et al. \(2016\)](#).

Our model assumes that firms’ cash flows are fixed and a change in BMI affects firm value through the discount rate. So we investigate whether the firms’ cash flows change in response to the Russell reconstitution. In Table 27 in the Appendix, we perform reduced-form tests for the fundamental variables associated with cash flows average over the three years following the reconstitution. We find little evidence that any of them is significantly different for the treated and control groups.⁶²

Although our model does not suggest any changes in risk factor loadings, we check if they change with the Russell index membership. We find no robust changes in either Fama-French-Carhart, Fama-French 5-factor, or Pastor and Stambaugh (2003) loadings.⁶³ In some specifications, loading on size factor increases upon addition to the Russell 2000. Since the size factor performed well in our sample period, this loading change should be associated with higher long-run returns. Hence, it could only prevent us from finding the long-run negative effect on risk premium.

Another alternative explanation for our long-run results could be that returns of firms that have transitioned to the Russell 2000 are lower because these firms have fallen on hard times and their cash flows are deteriorating. If this momentum continues, it is not surprising to see that the firms added to the Russell 2000 have lower future returns relative to firms that stayed in the Russell 1000. Our baseline controls (specifically, past returns) and the reported covariate tests are designed to alleviate this concern. Nonetheless, we took further steps to ensure this explanation is ruled out.

In addition to the covariate imbalance tests, we have checked explicitly whether any of the firms moving to the Russell 2000 are in financial distress. First, in our dataset, treated and control firms have similar Altman Z-scores and the scores do not change upon index reconstitution. Moreover, excluding firms classified by Altman Z-score as being ‘in distress’ or ‘in the grey zone’ does not change either the significance or magnitude of our results. Second, we tried excluding firms that ever filed for bankruptcy or experienced credit rating downgrades. We have also experimented with excluding firms that had a rapid deterioration in their market value rank prior to reconstitution. While our baseline analysis excludes jumps of 500 ranks, we have tried excluding firms that lost even as little as 100 ranks. Our

⁶²Apart from the reported characteristics, we inspected all characteristics summarized in Lewellen (2015). We find some support for lower asset growth of stocks added to (or not deleted from) the Russell 2000 but that would only bias us against finding our long-run result. Furthermore, we observe a higher turnover of these stocks so we link it to the rebalancing of benchmarked funds (see Section 4). However, stock liquidity, as measured by both ILLIQ of Amihud (2002) and bid-ask spread, deteriorates. In the literature, this is associated with higher expected returns, which is opposite to what we find.

⁶³This analysis involves estimating our reduced form specification with the future loadings on the left-hand side and controlling for lagged (pre-event) loadings. All loadings are 5-year computed from monthly rolling regressions of stock excess returns on factor returns available from Ken French’s website or WRDS, with a minimum of 2 years of data required for estimation.

results remained qualitatively unchanged, albeit the magnitude of the effect was smaller.

5.4.2 Further Remarks on Identification Approach

Our identification approach avoids several problems that have been highlighted in the literature (e.g. [Wei and Young \(2017\)](#)). Specifically, we do not use June weights for assignment or sample selection. Moreover, our proprietary ranking variable and robustness with 3SLS alleviate questions regarding the conditional exogeneity assumption.⁶⁴

Furthermore, the variation in BMI does not conflict with the known discontinuities around the Russell cutoff. That is, the local variation in total institutional ownership (IO), passive IO, benchmarked IO, and ETF ownership are implicit in the construction of our measure. They are also assumed to be time-varying since the amount of capital linked to indices changes (shown in Table 16 in the Appendix) and new indices emerge. Therefore, BMI is a unifying measure that implies some variation in all aforementioned variables; whether it is more pronounced in a particular sample depends on the distribution of assets between benchmarks.

5.4.3 Time Fixed Effects and Double-Clustering

Our baseline specification does not include year fixed effects, even though our goal is to compare the returns in the cross-section. We exclude them mainly because our analysis separates additions and deletions samples and there is an insufficient number of treated firms by year within them (as shown in Appendix, Table 6).

At the same time, for the year fixed effects to play a role in our experiment, there has to be a differential impact on the treated and control groups. That is, since we are comparing firms that switched indices with the firms that stayed, the estimate will be biased without year fixed effects only if the treated group is affected in a systematically different way than the control group. We discuss below that the covariates are balanced, which indicates that this concern is not very strong in our sample.⁶⁵

For illustration only, we report the results of estimating a reduced form specification with 3-year fixed effects in Table 25 in the Appendix. The significance is weaker but the sign is negative for all horizons, in line with our main specification. The reduced form for our specification is (9) with D_{it}^{2000} (index membership dummy) used instead of \widehat{BMI}_{it} .

⁶⁴As we discussed above, the assignment prediction quality is very high. Moreover, as a robustness check, we use a prediction step to orthogonalize any remaining measurement error (similar to [Ben-David et al. \(2018\)](#)).

⁶⁵Nevertheless, because our theory suggests the role for differential fundamental loadings (β_i in (2.1)), we report the estimation results for CAPM abnormal long-run returns in the Appendix (Table 30). It alleviates the concern that our results are driven by differential market exposure of the control and treated groups.

The reported t-statistics are based on standard errors clustered by stock. Double-clustering does increase the standard errors but most of the results remain significant at 5%. Since the prediction of the model is that the sign of β_0 is negative, our inference is based on a one-sided test with $H_a : \beta_0 > 0$. Of course, the one-sided tests do not change the reported t-statistics.

5.4.4 Flippers

We considered excluding stocks that moved between the Russell 1000 and 2000 indices more than once in five years – the so-called ‘flippers’. Our theoretical predictions concern stocks that joined a set of indices and stayed in them until the end of the investment horizon. Our results are considerably stronger, both statistically and in magnitude, if we drop stocks that moved between the Russell 1000 and 2000 indices more than once in the relevant horizon.⁶⁶ Economically, our theory would predict that the BMI of such flippers would change when they move index again and hence distort the long-run returns upwards. Moreover, fund managers, especially those who can take on more tracking error risk, could be able to identify stocks that move back and avoid trading them in the first index reconstitution to avoid transaction costs.

From the formal statistical perspective, however, excluding flippers introduces a selection bias. A stock which was added to the Russell 2000 index has to appreciate in value to come back to the Russell 1000 the next year. Therefore, by excluding flippers, we naturally exclude stocks with the most positive return realizations, which biases our β_0 estimate downward.

We believe that an analysis of any long-run variable using the Russell cutoff has to weigh these potential biases. At least, it has to take into account future index membership changes. In our case, the main reported results do not exclude flippers from the sample and hence represent the upper bound on β_0 coefficient.

5.4.5 Covariate Balance

In this section, we show that the other observed characteristics are smooth for firms around the cutoff. That is, we test for the differences in fundamental firm characteristics determined prior to the Russell reconstitution. We do it by estimating specification (9) with index dummy D^{R2000} instead of BMI (baseline controls are included) separately for additions and deletions samples. The dependent variable in this specification is a fundamental firm characteristic. We ensure that the data we use is released to the public by the rank day in

⁶⁶Reduced form regression results are reported in Tables 25 and 26.

May.

The results are in Table 32 in the Appendix. None of the imbalances is robustly significant. Moreover, we cannot think of an economic story why, say, repurchases should be significant for additions but not for deletions and enter with different signs before and after 2007. Nonetheless, in unreported analyses, we control for each of the imbalances and find no change to our results.

Apart from the reported characteristics, we considered additional characteristics shown to predict returns for U.S. stocks in the cross-section (summarized in Lewellen (2015)) as well as factor loadings (CAPM, Fama-French-Carhart, Fama-French 5, Pastor-Stambaugh, and standalone benchmark betas, e.g. with respect to the Russell 1000) and liquidity measures (ILLIQ of Amihud (2002), Return-to-Turnover of Florackis et al. (2011), and effective spread of Abdi and Ranaldo (2017)). The only measures that appear imbalanced are the bid-ask spread, stock volatility, past year stock return, and CAPM beta. We, therefore, include them as controls in our baseline specification, dropping volatility as it turns out to be insignificant and have no effect on our estimates.⁶⁷

6 Conclusion

In this paper, we propose a measure that captures inelastic demand for a stock – benchmarking intensity. Exploiting a variation in the benchmarking intensity of stocks moving between the Russell 1000 and Russell 2000 indices, we document the effects of BMI on stock prices, expected returns, ownership, and demand elasticities.

We find that stocks with higher benchmarking intensities have higher prices and lower expected returns. Even though we focus on the evidence from the quasi-natural experiment offered by the Russell 1000/2000 reconstitution, BMI is a stock-level characteristic and the predictions of our theory can also be tested with the usual methods of cross-sectional asset pricing. We leave this for future research.

Our measure reflects the inelastic demand of both active and passive funds for stocks in their benchmarks. According to our preferred habitat view, active funds are not genuinely active investors. Rather, they simply deviate from their benchmarks to a larger extent than passive funds. In our sample, active funds own large fractions of shares outstanding, higher than passive funds, and that is why they contribute significantly to the aggregate inelastic demand for benchmark stocks. On average, a large part of active funds' holdings is in benchmark stocks, both in terms of the number of stocks and AUM share. Because of this,

⁶⁷The results are also robust to using polynomial controls as well as controls interacted with the index membership dummy (polynomial and linear).

our framework has important implications for measuring the price elasticity of demand for stocks. BMI helps overcome the challenge posed by the presence of an inelastic component in active managers' demand. The demand elasticities differ from those in the previous research based on index inclusions because the literature has not accounted for the inelastic component in active managers' demand and the heterogeneity of benchmarks.

We find evidence of the inelastic demand of active managers in the ownership data. Studying the rebalancing around the Russell cutoff, we document that both active and passive managers buy additions to their benchmarks and sell deletions.

Our model abstracts from transaction costs but, in practice, they are important. To save on transaction costs, fund managers often engage in the so-called optimized sampling, which leads to exclusion of some of the smallest stocks in the benchmark from the funds' portfolios. We discuss how it interferes with the incentives to hold the benchmark portfolio and may affect our results. We leave the detailed analysis of how exactly optimized sampling affects benchmarking for future research.

A Appendix

A.1 Assets Benchmarked to Indices

Figure 5: Assets benchmarked to indices

This figure shows the evolution of the share of benchmark groups in the total assets under management of US domestic equity mutual funds. Mid- and small-cap stocks are in 75th – 95th percentile of market capitalization. All reported indices include blend, value and growth types, e.g. Russell 1000 above represents the sum of the Russell 1000, Russell 1000 Value, and Russell 1000 Growth. CRSP indices were launched in 2012 when Vanguard switched from MSCI indices. In the graphs, we show the share of CRSP after 2012 and corresponding MSCI indices before 2012. The group of ‘other benchmarks’ consists of such indices as Dow Jones, FTSE, and Wilshire as well as smaller benchmarks that we do not differentiate among.

A.2 Details on Data

Stock data comes from standard sources. We take daily returns, prices, adjustment factors, and bid and ask prices from CRSP.⁶⁸ Market, risk-free rate, and factor returns are from Ken French’s Database. All fundamental accounting data comes from Compustat. We use CRSP-Compustat linking table and take into account release dates to make sure that the variables are available to the public by the rank date in May.

In fund rebalancing analyses, we use holdings available in the CRSP Mutual Fund Database (CRSP, June 2010 - December 2018) and Thomson Reuters S12 (TRS12, March 1980 - December 2018). Our main source is TRS12 and we use CRSP to add funds for

⁶⁸Returns are adjusted for delisting in a standard way.

which data is not available in TRS12. Moreover, CRSP is used to validate the net assets of the funds and pull various fund-level characteristics, such as returns, expense ratios, equity percentage, and others. We merge the databases using MFLINKS following steps described in Section A.4 in the Appendix. We follow several data validation procedures and impose typical mutual fund filters, which are outlined in the Appendix as well (Section A.6). Mutual-fund ownership share for any stock is computed as the percentage of shares held by funds of a certain type in the total number of shares outstanding for the stock (using TRS12 and CRSP as above).

We classify funds into active and passive based on the *index_fund_flag* in CRSP and by screening fund names. All ETFs in our sample are classified as passive. A fund is classified as an ETF if its *et_flag* in CRSP is non-empty or it has *exchange-traded* or *etf* in its name. We manually resolve and exclude exceptions when the same portfolio has share classes of both active and passive funds. Detailed steps as well as the textual rules we deploy for the screening are listed in Section A.8 of the Appendix.

We use daily fund returns from CRSP and benchmark returns from Morningstar in order to compute tracking errors (net).

A.3 Construction of the Historical Benchmarks Data

We manually assemble a dataset of historical mutual funds benchmarks from the following sources:

1. Snapshot of benchmarks (*primary_prospectus_benchmark* field) in Morningstar as of September 2018.
2. Database of historical fund prospectuses available on the website of the U.S. Securities and Exchange Commission (SEC)⁶⁹.
3. SEC Mutual Fund Prospectus Risk/Return Summary⁷⁰ data sets (MFRR). Benchmarks are mentioned in the annual return summary published in prospectuses.

We use the *crsp_fundno*-CIK mapping from CRSP to link CIK, SEC identifiers, back to *crsp_fundno*. To map CRSP and Morningstar, we mostly follow the procedure in Pastor et al. (2015), details are below in Section A.5.

⁶⁹Follow SEC’s mutual fund search page: <https://www.sec.gov/edgar/searchedgar/mutualsearch.html>

⁷⁰Follow the MFRR page: <https://www.sec.gov/dera/data/mutual-fund-prospectus-risk-return-summary-data-sets>.

A.3.1 Scraping the EDGAR and Building Text-Based Series

Mutual funds are required to regularly submit filings to the SEC. The SEC’s EDGAR system stores filings in electronic archives since 1994. Even though the SEC Rule S7-10-97⁷¹ required funds to report their benchmark (or a ‘reference broad market index’) in prospectuses from December 1, 1999, some funds voluntarily did so prior to that (Sensoy (2009)). Reporting of manager compensation contracts was required by the SEC Rule S7-12-04⁷² starting in the October of 2004. Therefore, the procedure discussed below will cover the history of filings for any particular fund back to 1998.

The filings that include information on fund benchmark and manager compensation are N-1A/485 (registration statement including a prospectus), 497K (summary prospectus), 497 (fund definitive materials), and 497J (certification of no change in definitive materials). All of these can be accessed via package ‘edgarWebR’ available in R.⁷³ Since the holdings data set is already linked to CRSP fund identifiers (*fundno*), we will use all CIK codes⁷⁴ available in the mapping file *crsp_cik_map*. For each CIK, we retrieve a list of all historical filings (485 and 497/497K/497J forms) using *company_filings()* function. Then we parse the filings into raw text format using *parse_filing()* function.

Having obtained the filings for each CIK and each filing date, we re-organize the data set into a panel: quarterly text files for each fund. To do so, we assign observations with a 497J form a ‘no-change’ tag. Moreover, after looking at the text data, we assign a ‘no-change’ tag to 497 forms with no reference to benchmark or manager compensation.⁷⁵

Before extracting the data, each of the filings is tokenized (we work with both tokenized text and string formats) and de-capitalized, punctuation and certain stop words are removed.⁷⁶ All these steps are done using NLTK⁷⁷ module in Python. Afterwards, we classify all 485 and 497K documents as prospectuses, while we have to look into the content of 497 filings to classify them into prospectuses or statements of additional information (SAI). Typically, funds specify the type of the document in the header, we therefore search for the exact match (‘prospectus’ or ‘statement of additional information’) in the first 100 characters

⁷¹Available on: <https://www.sec.gov/rules/final/33-7512r.htm>.

⁷²Available on <https://www.sec.gov/rules/final/33-8458.htm>.

⁷³Description is available on: <https://cran.r-project.org/web/packages/edgarWebR/index.html>.

⁷⁴The Central Index Key (CIK) is used as the main identifier of the filing entities on the SEC’s EDGAR and available per fund, fund series, and fund company. We first use series CIK as benchmarks differ at this level, then we use company CIK to fill in any missing observations.

⁷⁵Since fund prospectus is a legal document and fund clientele supposedly depends on it, we see that prospectuses are relatively ‘sticky’ and hence the time series for most of the funds looks like ‘prospectus’ definition at an early date and then at most 1-2 changes for the fund history.

⁷⁶Numerical data and special characters cannot be removed though as they are included in benchmark names. Moreover, we retain negation.

⁷⁷Official page is: <http://www.nltk.org/>.

of the filing.

There are a few challenges we face when extracting the fund benchmark from prospectus text. Even though all funds are required to disclose the benchmark, they tend to do it in a very different manner. Some funds explicitly say that the performance can be evaluated against a particular market index, some only report the index performance below the required performance tables (as an implicit benchmark). If referring to the benchmark in the text, funds do not use standardized language: some may say ‘benchmark’, some ‘market index’ or ‘reference index’ and some may omit the term and only use a phrase similar to ‘performance is measured against’. Moreover, some funds may define a mixture of indices as their benchmark, e.g., ‘60% Russell 1000, 40% Russell 2000’. Therefore, we are faced with the task of extracting information from unstructured text.

Finally, in some cases, we need to first isolate the text to extract the benchmark name from. Fund families may choose to submit one prospectus for many funds. Within one prospectus document, many funds can either share the same section or each fund can have a separate section. We therefore extract the fund-relevant part of prospectus whenever possible (typically in the second case only). To do so, we search for the fund name and the fund ticker in the text. Most commonly, the relevant section starts with a ticker/name and has it repeated on each page throughout the section. We hence extract the part of the text with the highest density of tickers/fund names.

When extracting benchmarks from the (isolated) text, we use a set of rules that maximizes the chance of the algorithm picking up the benchmark correctly. The set of rules includes but is not limited to:

- Search for a benchmark provider name from the list (de-capitalized already): *{s&p, russell, crsp, msci, dj, dow jones, nasdaq, ftse, schwab, barclays, wilshire, bridgeway, guggenheim, calvert, kaizen, lipper, redwood, w.e. donoghue, essential treuters, barra, ice bofaml, bbgbarc, cboe}*.⁷⁸ If a benchmark from the list is found, retrieve the subsequent 40 characters to extract the full benchmark name. Match the full names using the list from Morningstar (for example, *russell 1000 value tr usd*).
- If several matches are established, we record the number of matches and each benchmark name (with subsequent characters, as above).
- We also search for words from the list (*context words*): *{index, benchmark, reference, performance, relative, return, measure, evaluate, assess, calculate}*. We use these words

⁷⁸This list has been compiled using the Morningstar benchmark snapshot. It is survivorship-bias free. According to Morningstar, the first three providers take over 90% of the market and the first five - around 98%.

in two ways. Firstly, if a benchmark name match is established, we check if any of these *context words* is present within 100 characters around the name. Secondly, if no match is established, we record pairwise distance in letters between benchmark names and *context words* and return the pair with minimum distance. This second approach is based on the string format of the text and required if the match was not established due to imprecision in tokenization.

We manually clean the extracted data to remove typos and map it to full benchmark names. In the resulting sample of quarter-fund-benchmarks, we manually verify all funds that got matched with several benchmarks or that had a benchmark change. Subsequently, we validate a random sample of funds through manual analysis of the prospectus text. We also compare the benchmarks as of September 2018 with a snapshot we obtained from the Morningstar database and manually resolve any mismatch. Furthermore, we compare a time series we get with a series available for a small sample of funds in MFRR.

As expected, prospectuses are relatively sticky. In the entire sample over 1998-2018, we observe 1,208 changes at a share class level (around 300 at master fund level). The largest benchmark change in terms of tracking assets for passive funds in Vanguard’s move from MSCI to CRSP indices in 2012 and 2013. For active funds, it is T. Rowe Price’s change from the S&P 500 to Russell 1000 Value and Growth indices in 2018.

A.4 CRSP and Thomson Reuters S12 Merge Procedure

We use Mutual Fund Links (MFLINKS) to merge CRSP and TRS12 similar to the procedure described in [Doshi et al. \(2015\)](#).

Firstly, we prepare TRS12 holdings:

- keep last holdings report for each fund in a given month,
- match WFICN number from MFLINKS to fundno, rdate, and fdate in TRS12 file,
- when there are duplicate reports for the same date, keep the fund with the largest assets,
- pull CRSP stock files and adjust reported number of shares by the correct adjustment factor - as of rdate.

Then, we prepare CRSP holdings:

- clean the data based on portnomap to ensure that only one portno is valid for a particular date for any fund (remove overlaps in the data due to mergers),
- match WFICN number from MFlinks to crsp_fundno,
- clean overlaps in wficn-portno mapping,
- keep the last report for every month.

Finally, we stack the two parts and remove duplicate entries from CRSP (at a fund

level).

A.5 CRSP and Morningstar Merge Procedure

The merge procedure is a slight modification of [Pastor et al. \(2015\)](#).⁷⁹

A.6 Asset Validation

TNA and holdings data are generally validated by MFLINKS (only funds with sufficient match quality are linked). However, we additionally validate the TNA in order to ensure a better match with the holdings. In the case of CRSP, we use the sum of assets across share classes and weigh share class level data such as equity percentage by the fraction of total assets this share class represents. Because TRS12 reports only equity and CRSP reports all assets, we multiply the most recent equity percentage by CRSP assets. We use the following for validation:

- compare the total dollar sum of holdings in the merged file with the assets reported by TRS12 and CRSP and call the difference ‘unexplained’,
- if the difference between TRS12 and CRSP is smaller than 1%, we use CRSP,
- if CRSP has lower unexplained or TRS12 does not report assets, we use CRSP and otherwise TRS12.

A.7 Filtering

In the final sample, we keep only funds that:

- have fund-quarter entries where I validated the assets at 20% precision;
- are either active or passive domestic equity funds that did not change its style or objective over their history (see details below in Section [A.8](#));
- have an average common equity percentage between 50 and 120%;
- have more than USD 1 million in assets.

A.8 Active and Passive Domestic Equity Funds

We follow the major steps of the procedure described in [Doshi et al. \(2015\)](#) to filter out active domestic equity funds and augment it to identify passive funds better.

We use *crsp_obj_cd* (CRSP objective code) to identify ‘equity’, ‘domestic’, ‘cap-based or style’ and exclude ‘hedged’ and ‘short’ and remove those funds that changed their

⁷⁹Details are available upon request.

objectives. I also only keep funds with 'ioc' variable in TRS12 file (investment objective) not in (1,5,6,7). Active funds are identified as those without '*Index_fund_flag*' or with '*B*' (index-based funds) and without '*et_flag*'. I also exclude funds that have a range of words in their names, as per the list below.

List of n-grams to exclude from active funds names (all in lower case).

1. Generic and index provider names: index, indx, ' idx ', s&p, ' sp ' (with spaces), nasdaq, msci, crsp, ftse, barclays, ' dj ', ' dow ', jones, russell, ' nyse ', wilshire, 400, 500, 600, 1000, 1500, 2000, 2500, 3000, 5000
2. Passive management names: ishares, spdr, trackers, holdrs, powershares, streettracks, ' dfa ', 'program', etf, exchange traded, exchange-traded
3. Target fund names: target, retirement, pension, 2005, 2010, 2015, 2020, 2025, 2030, 2035, 2040, 2045, 2050, 2055, 2060, 2065, 2070, 2075

Our sample of passive funds consists of index funds and ETFs available on CRSP. Index funds are those with '*index_fund_flag*' of '*D*' or '*E*' and those that include a range of words in their name:

1. Generic and index provider names: index, indx, ' idx ', s&p, ' sp ' (with spaces), nasdaq, msci, crsp, ftse, barclays, ' dj ', ' dow ', jones, russell, ' nyse ', wilshire, 400, 500, 600, 1000, 1500, 2000, 2500, 3000, 5000
2. Passive management names: ishares, ' dfa ', 'program'

ETFs are those with not missing '*et_flag*' or having '*etf*', '*exchange – traded*', '*exchangetraded*' in their name:

1. Passive management names: spdr, trackers, holdrs, powershares, streettracks, etf, exchange traded, exchange-traded

Target funds are those with target years in the name, e.g., '2015' and '2075', or 'retirement', 'target'. Creating a clean sample of target funds potentially requires different treatment of objective codes (see CRSP Style Guide). Since we only aim to exclude them, we remove fund with the following n-grams in their names:

1. Target fund names: target, retirement, pension, 2005, 2010, 2015, 2020, 2025, 2030, 2035, 2040, 2045, 2050, 2055, 2060, 2065, 2070, 2075

We exclude all leverage and inverse funds by identifying the following n-grams in the names: *'leverage'*, *'inverse'*, *'2x'*, *'1.5x'*, *'1.25x'*, *'2.5x'*, *'3x'*, *'4x'*.

If we apply the rules above, some of the funds in the sample will include both active and passive share classes. We clean the resulting sample of funds with share classes of different types as per the rule: (a) Put ETF shares of index funds as ETFs (passive type maintained). (b) When missing the flag for otherwise index funds and portno is the same, set to index. (c) If *portno/cl_grp* are different, exclude.

The remaining funds are further filtered based on the common equity percentage as discussed in [A.7](#).

A.9 Russell Reconstitution

Russell indices undergo a yearly reconstitution at the end of June. The reconstitution is a two-step process: assigning a stock to an index and determining the weight of the stock in that index.

The first step is solely based on the ranking of all eligible securities by their total market capitalization on the rank day in May. For most of the years in our sample, the rank day falls on the last trading day in May⁸⁰. Russell uses its broadest Russell 3000E index as the universe of eligible securities together with newly admitted stocks⁸¹. Ranks are computed based on the proprietary measure of the total market capitalization of eligible securities. This proprietary measure has been made available to us by Russell⁸²⁸³ and hence we are able to replicate the assignment rule very closely.⁸⁴

In the second step, each stock in the index is assigned a weight based on its float-adjusted market capitalization. To define the adjustment, Russell uses proprietary float factors, which we can infer from total and float-adjusted market capitalization. These factors do not affect index assignment but they explain some variation in the benchmarking intensity due to their direct relationship with index weights: all else equal, stocks will have lower index weight if the float adjustment is larger, and hence lower BMI.

Before 2007, a firm would be assigned to the Russell 2000 index if and only if its total market value rank falls between 1000 and 3000. Since the assignment is based on ranks,

⁸⁰Exceptions are recent years, when the rank days were: 05/27/2016, 05/12/2017, and 05/11/2018.

⁸¹See the details on the methodology in the official and publicly available guide.

⁸²We match this measure to the May Russell 3000E constituent lists as well as the preliminary constituent lists from June in order to arrive at the universe of eligible securities. The preliminary lists have also been provided by Russell.

⁸³We performed our analysis with the market value measure constructed from CRSP and Compustat as in [Chang et al. \(2014\)](#) as well. This measure delivers qualitatively identical main results.

⁸⁴For comparability with other papers, we include a Table ?? in the Appendix.

firms cannot manipulate it.⁸⁵ Moreover, an idiosyncratic shock to the market value on the rank date can bring the stock to the other side of the cutoff. Hence, the assignment is as good as random.

In order to reduce the turnover between indices, FTSE Russell introduced a ‘banding’ policy in 2007. According to the new rule, a stock is assigned to the Russell 2000 index if and only if:

- it was in the Russell 2000 in the previous year and its total market value rank in May falls between the left cutoff $(1000 - c_1)$ and 3000⁸⁶
- it was in the Russell 1000 and its total market value rank in May falls between the right cutoff $(1000 + c_2)$ and 3000.

The band, that is, the range of ranks between $(1000 - c_1)$ and $(1000 + c_2)$, is still based on a mechanical rule but it changes each year with the distribution of firm sizes around the cutoff.⁸⁷ Because of banding, the turnover between indices went down significantly, as intended.⁸⁸ We list the number of additions and deletions per year in Table 6.

⁸⁵Typically, bunching is formally tested for with McCrary (2008) test but since the assignment variable is a rank, which is relative to other stocks, bunching is not possible.

⁸⁶The rule is similar for stocks moving to the Russell 2000 from below, i.e., around rank 3000. We are omitting it here for brevity.

⁸⁷Specifically, it is a 5% band around the cumulated market cap of the stock ranked 1000 in Russell 3000E universe on the rank date.

⁸⁸Russell’s analysis is available online: <https://www.ftserussell.com/blogs/russell-2000-recon-banding-results-lower-turnover>.

Table 6: Historical Details on Russell 2000 Reconstitution

Year	Additions	Deletions	Russell 1000		Russell 2000	
			Smallest	Smallest w/banding	Largest w/banding	Largest
1998	57	54	1.4			1.4
1999	59	70	1.4			1.4
2000	50	48	1.6			1.5
2001	86	104	1.4			1.4
2002	78	73	1.3			1.3
2003	43	56	1.2			1.2
2004	49	38	1.6			1.6
2005	61	58	1.8			1.7
2006	49	68	2.0			1.9
2007	5	15	2.5	1.8	3.1	2.5
2008	31	38	2.0	1.4	2.7	2.0
2009	36	39	1.2	0.8	1.7	1.2
2010	14	25	1.7	1.3	2.2	1.7
2011	23	35	2.2	1.6	3.0	2.2
2012	27	32	2.0	1.4	2.6	1.9
2013	27	30	2.5	1.8	3.3	2.5
2014	28	24	3.1	2.2	4.1	3.1
2015	48	20	3.4	2.4	4.3	3.4
2016	48	34	2.9	2.0	3.9	2.9
2017	40	31	3.4	2.3	4.5	3.4
2018	35	48	3.7	2.5	5.0	3.7

This table reports the number of additions to and deletions from Russell 2000. We only report deletions which moved to Russell 1000, not those that moved down in the ranking. The last four columns report the market value (in billions USD) of smallest and largest stocks in the indices.

A.10 Instrument Strength

Russell 2000 membership is associated with a considerable increase in the benchmarking intensity: the estimates range between 0.05 and 0.13. This represents a large change as the sample standard deviation of BMI within each index around the cutoff is 0.10 (Table 8). High F-statistics support the relevance of our instrument.

Table 7: First stage regression results

	Benchmarking intensity							
	1998-2006 sample		2007-2018 sample		1998-2006 sample		2007-2018 sample	
	Additions	Deletions	Additions	Deletions	Additions	Deletions	Additions	Deletions
D^{R2000}	0.07*** (14.20)	0.07*** (17.25)	0.05*** (9.84)	0.07*** (14.32)	0.07*** (10.71)	0.08*** (13.44)	0.07*** (11.38)	0.13*** (14.91)
Band width	300				100			
Ranking variable ($\log MV$)	Yes				Yes			
Other controls (\bar{X})	Yes				No			
Observations	2035	2438	1242	1968	650	948	356	645
Coef. F-stat.	202	298	97	205	115	181	130	222
Adjusted R ² , %	30	37	49	49	17	19	27	25

This table reports the results of the first stage regression (8) for stocks in the pre-banding (1998-2006) and the post-banding (2007-2018) samples. The dependent variable is the benchmarking intensity of stock i as of September in year t , BMI_{it} . The key independent variable, D_{it}^{R2000} , is the Russell 2000 index membership dummy of stock i as of June in year t . We include only stocks that were in the Russell 1000 (additions) or Russell 2000 (deletions) in the previous year. Both coefficients have positive sign as the treated are the firms that remained in the Russell 2000. Band width is 300 or 100 stocks around the relevant cutoffs. Other controls (\bar{X}) include a float factor control, a 5-year monthly rolling stock beta computed using the CRSP total market value-weighted index, a 1-year monthly rolling average bid-ask percentage spread, and stock's return over year $t - 1$. t-statistics based on standard errors with clusters at a stock level are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

An interesting insight from the first stage regression is the asymmetry of the cutoffs after 2007. Looking at the specification with a narrower band, prior to the introduction of banding, Russell 2000 membership explained around 0.08 difference in the intensity between stocks on different sides of the cutoff. After 2007, this number increased to 0.13 around the left cutoff (for deletions) and remained the same around the right cutoff (for additions). This observation mirrors the relative distance between red and grey lines in Figure 3 (d) in the main text: the distance is larger for the left cutoff, i.e., for the stock ranked around 825, as opposed to than the right cutoff, i.e., the stock ranked around 1250.

A.11 Descriptive Statistics

Table 8: Descriptive statistics around the cut-off

	<i>Stocks in Russell 1000</i>					<i>Stocks in Russell 2000</i>				
	Obs.	Mean	St.Dev.	Min	Max	Obs.	Mean	St.Dev.	Min	Max
BMI	3,496	0.17	0.09	0.00	0.57	4,688	0.21	0.12	0.00	0.80
Average long-run excess return, % (winsorized at 1%):										
<i>12-month</i>	3,307	1.09	2.81	-11.18	12.28	4,430	1.05	2.74	-11.18	12.28
<i>24-month</i>	3,033	0.92	1.97	-7.11	8.35	4,003	0.98	1.97	-7.11	8.35
<i>36-month</i>	2,760	0.90	1.56	-4.86	6.34	3,623	0.97	1.52	-4.86	6.34
<i>48-month</i>	2,509	0.90	1.29	-3.76	5.51	3,289	0.92	1.30	-3.76	5.51
<i>60-month</i>	2,269	0.95	1.15	-3.04	4.83	3,006	0.94	1.16	-3.04	4.83
Average periodic excess return, % (winsorized at 1%):										
<i>0-12 months</i>	3,307	0.63	2.83	-15.04	9.27	4,430	0.61	2.89	-15.04	9.27
<i>12-24 months</i>	3,033	0.88	3.11	-14.26	8.84	4,005	0.25	2.99	-14.26	8.84
<i>24-36 months</i>	2,761	-0.01	3.06	-13.39	8.73	3,627	0.20	3.05	-13.39	8.73
<i>36-48 months</i>	2,512	0.18	2.96	-12.73	8.51	3,294	0.09	3.05	-12.73	8.51
<i>48-60 months</i>	2,275	0.28	2.90	-11.98	8.30	3,012	0.32	2.95	-11.98	8.30
Bid-ask spread, %	3,505	0.15	0.15	0.00	2.85	4,702	0.15	0.17	0.00	4.68
β^{CAPM} (winsorized at 1%)	3,317	1.10	0.73	-0.08	3.56	4,475	1.13	0.75	-0.08	3.56
Market value (Russell)	3,538	2018	620	534	3908	4,759	2010	1037	798	9592
Last-year return, % (winsorized at 1%)	3,427	2.83	37.90	-82.05	246.90	4,648	28.62	49.90	-82.05	246.90

This table reports the descriptive statistics of the main stock-level variables used in the analysis – by index the stock belongs to in the current year. These statistics are calculated on 300 stocks around the cutoff in 1998-2018. All returns are monthly.

A.12 Instrumenting Index Membership

Table 9: First stage regression results for 3SLS

	D_{it}^{R2000} : stock \in Russell 2000 index							
	<i>1998-2006 sample</i>		<i>2007-2018 sample</i>		<i>1998-2006 sample</i>		<i>2007-2018 sample</i>	
	<i>Additions</i>	<i>Deletions</i>	<i>Additions</i>	<i>Deletions</i>	<i>Additions</i>	<i>Deletions</i>	<i>Additions</i>	<i>Deletions</i>
τ_{it}	0.963*** (110.32)	0.964*** (118.41)	0.964*** (98.93)	0.949*** (86.19)	0.953*** (92.37)	0.950*** (81.67)	0.923*** (59.86)	0.906*** (42.82)
Band width	300				100			
Ranking variable ($\log MV$)	Yes				No			
Observations	2,181	2,652	1,343	2,096	958	657	650	356
F-statistic	30,147	25,953	7,223	14,982	8,532	6,670	3,583	1,834
Adjusted R^2 , %	95	96	90	91	91	89	82	79

This table reports the results of the first stage regression (in a 3SLS) for stocks in the pre-banding (1998-2006) and the post-banding (2007-2018) samples. The dependent variable is the dummy for Russell 2000 membership of a stock i as of June in year t . We include only stocks that were in Russell 1000 (additions) or Russell 2000 (deletions) in the previous year. Band width is 300 or 100 stocks around the cutoffs (rectangular kernel). t-statistics based on HAC-robust standard errors with clusters at a stock level are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.13 Index Effect and Predicted BMI Change

For consistency with Section 5.1, we estimate the following specification:

$$\begin{aligned}\Delta BMI_{it} &= \gamma_0 D_{it}^{RU2000} + \gamma_1 \log MV_{it} + \delta'_1 \bar{X}_{it} + \varepsilon_{1it} \\ Ret_{it}^{June} &= \beta_0 \widehat{\Delta BMI}_{it} + \beta_1 \log MV_{it} + \delta'_2 \bar{X}_{it} + \varepsilon_{2it}\end{aligned}\tag{10}$$

In the above specification, D^{RU2000} is 1 when stock i is in the Russell 2000 on the reconstitution day in June of year t . Ret_{it}^{June} is the return of stock i in June of year t , winsorized at 1%. ΔBMI_{it} is a difference between the BMI of stock i in May of year t and its deflated BMI in June of the same year. Deflated BMI is computed using index AUM shares in June but weights as of May; that is, it accounts for the new index membership of stock i but not its return in June. We deflate BMI because otherwise the actual June index weights will include the (post-announcement) price pressure and mechanically exhibit a positive relationship with June returns. $\log MV$ is the logarithm of total market value, the ranking variable as of May provided by Russell. \bar{X} is a vector of other controls that we include for consistency, they are the same as in other analysis. We estimate this specification for additions and deletions separately.

Table 10: Change in BMI and price pressure in June

	Return in June			
	Additions	Deletions	Additions	Deletions
$\widehat{\Delta BMI}_{it}$	0.53*** (5.76)	0.22*** (5.37)	0.25** (2.20)	0.19*** (3.56)
Band width	300		100	
Ranking variable ($\log MV$)	Yes		Yes	
Other controls, \bar{X}	Yes		No	
Observations	3,282	4,410	1,010	1,617
Adjusted R^2 , %	14	14	2	2
First-stage coefficient	0.06*** (34.43)	0.10*** (41.28)	0.07*** (27.81)	0.10*** (33.07)
First-stage F-statistic	1,185	1,703	774	1,091
First-stage R^2 , %	38	50	57	56

This table reports the results of specification (10) for stocks in the full sample (1998-2018). The dependent variable is the winsorized return of stock i in June in year t . The key independent variable, $\widehat{\Delta BMI}_{it}$, is the predicted change in BMI between June and May deflated to May prices. Other controls \bar{X} are our baseline controls from Table 5. We include only stocks that were in Russell 1000 (additions) or Russell 2000 (deletions) in the previous year. Band width is 300 or 100 stocks around the cutoffs. t-statistics based on standard errors with clusters at a stock level are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.14 Index Effect in Our Sample

Table 11: Price pressure in June

	Return in June			
	<i>Additions</i>	<i>Deletions</i>	<i>Additions</i>	<i>Deletions</i>
D_{it}^{RU2000}	0.032*** (5.78)	0.018*** (4.72)	0.022*** (3.19)	0.024*** (4.90)
Band width	300		100	
Observations	3259	4389	937	1495
Adjusted R ² , %	22	20	25	23

This table reports the results of the reduced form specification of (10) for stocks in the full sample (1998-2018).^a The dependent variable is the winsorized return of stock i in June in year t . The key independent variable, D_{it}^{RU2000} , is the Russell 2000 index membership dummy, measured in June. All regressions include the ranking variable ($\log MV$) and other baseline controls \bar{X} . We include only stocks that were in Russell 1000 (additions) or Russell 2000 (deletions) in the previous year. Band width is 300 or 100 stocks around the cutoffs (rectangular kernel). t-statistics based on HAC-robust standard errors with clusters at a stock level are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

^aUsing the RDD specification in Chang et al. (2014) on our data delivers estimates close to those reported in this table.

A.15 Price Pressure and BMI – With Banding Controls

Table 12: Deflated BMI change and return in June, with banding controls

	Return in June						ΔBMI , %
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
ΔBMI	0.190*** (8.58)	0.157*** (5.80)	0.157** (2.29)				
ΔBMI quartile 1				-0.013*** (-7.94)	-0.011*** (-6.38)	-0.011*** (-3.72)	-18.5
ΔBMI quartile 2				-0.007*** (4.43)	-0.004** (-2.55)	-0.004* (-1.81)	-2.2
ΔBMI quartile 3				0.006*** (-0.80)	0.004** (2.32)	0.004** (2.53)	6.6
ΔBMI quartile 4				0.014*** (6.69)	0.008*** (3.84)	0.008** (2.77)	44.9
Controls	N	Y	Y	N	Y	Y

Observations	11,941	10,843	10,843	11,939	11,939	11,939	
R^2 , %	1.45	13.25	13.25	1.78	13.35	13.35	

This table reports the results of specification (5) for stocks in the full sample (1998-2018). The dependent variable is the winsorized return of stock i in June in year t (in columns (1)-(3) and demeaned by year in (4)-(6)). The independent variable is ΔBMI_{it} , the change in the BMI of stock i between June and May of year t deflated to May prices, or the dummies for its quartiles. Controls include $\log MV$, the ranking variable, and other controls, \bar{X} , demeaned by year in columns (4)-(6). The banding controls (previous index membership, being in the Russell band, and their interaction) are also demeaned by year in columns (4)-(6). Band width is 300 around rank 1000. The last column reports the mean percentage ΔBMI_{it} in each quartile. t-statistics based on clustered standard errors are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.16 Price Pressure and BMI in Narrower Bands

Table 13: Deflated BMI change and return in June, narrower band

	Return in June								ΔBMI , %	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
ΔBMI	0.122*	0.132**			0.187	0.201**				
	(1.79)	(2.51)			(1.52)	(2.13)				
ΔBMI quartile 1			-0.013***	-0.012***			-0.014***	-0.012***	-26.5	-17.9
			(-2.85)	(-3.12)			(-3.15)	(-2.99)		
ΔBMI quartile 2			-0.010**	-0.006*			-0.008*	-0.007*	-4.2	-2.6
			(-2.00)	(-1.94)			(-1.77)	(-1.69)		
ΔBMI quartile 3			0.006**	0.003*			0.011***	0.006**	6.7	8.3
			(2.15)	(1.84)			(3.53)	(2.37)		
ΔBMI quartile 4			0.017**	0.011**			0.012	0.008*	41.6	55.1
			(2.27)	(2.59)			(1.56)	(1.71)		
Band			100				100		100	100
Cutoff			Right				Left		Right	Left
Fixed effect	Year			NA	Year			NA		
Controls	N	Y	N	Y	N	Y	N	Y		
Observations	4,026	3,682	4,026	3,682	3,953	3,571	3,953	3,571		
Within R^2 , %	0.60	14.87	1.53	15.06	0.70	15.33	1.30	15.32		

This table reports the results of specification (5) for stocks in the full sample (1998-2018) in a narrower band. The dependent variable is the winsorized return of stock i in June in year t (in columns (1), (2), (5) and (6) and demeaned by year in (3), (4), (7) and (8)). The independent variable is ΔBMI_{it} , the change in the BMI of stock i between June and May of year t deflated to May prices, or the dummies for its quartiles. The last two columns report the mean percentage ΔBMI_{it} in each quartile. All regressions include the ranking variable, $\log MV$, and other controls \bar{X} , demeaned in columns (3), (4), (7), and (8). t-statistics based on standard errors clustered by stock and year are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.17 Elasticity Estimates

Table 14: Elasticity Estimates

Sample	Demand change, %	Elasticity estimates for index effect of:				
		2%	2.3%	3%	4%	5%
1998-2018	6.96	-3.48	-3.03	-2.32	-1.74	-1.39
1998-2012	5.56	-2.78	-2.42	-1.85	-1.39	-1.11

This table reports the sensitivity of our estimates of price elasticity of demand to the size of index effect. Elasticity is computed as: $-\% \text{ Demand change} / \text{Index effect } \%$. The average demand change values come from Table 15. Our estimate of price pressure in 1998-2018 is 2.3%. Second row reports the estimates for 1998-2012, sample closest to [Chang et al. \(2014\)](#), who find that the price pressure amounts to 5%.

A.18 Estimates of Demand Change by Year

Table 15: Demand change for additions to the Russell 2000

ΔBMI	Percentage demand change, %						Fraction passive, %
	Full (BMI)	All Russell	Russell 1000	Russell Midcap	Russell 2000	Active	Passive
1998	-0.03	-0.13	1.55	-1.57	-1.22	4.33	-0.01
1999	0.06	0.35	1.92	-1.90	-1.51	5.33	0.00
2000	0.19	1.21	3.20	-1.63	-1.94	6.77	0.03
2001	0.22	1.08	3.71	-1.89	-2.04	7.65	0.36
2002	0.43	2.09	5.46	-1.90	-2.17	9.53	0.69
2003	0.62	4.88	8.35	-1.74	-2.59	12.67	1.01
2004	0.70	6.51	7.39	-1.89	-3.41	12.70	1.14
2005	0.59	4.29	6.45	-1.79	-3.47	11.71	0.90
2006	0.66	5.58	7.04	-2.34	-3.81	13.20	1.22
2007	0.46	6.00	6.62	-2.55	-3.83	12.99	1.14
2008	0.46	7.19	8.36	-2.37	-4.89	15.62	1.93
2009	0.53	12.06	8.88	-2.02	-4.74	15.64	1.79
2010	0.61	9.74	9.67	-2.71	-4.28	16.66	1.48
2011	0.64	7.55	10.21	-2.90	-4.36	17.47	1.44
2012	0.74	15.02	9.93	-3.11	-4.95	17.98	1.82
2013	0.66	12.94	10.23	-3.26	-4.80	18.29	2.28
2014	0.59	11.24	8.38	-3.43	-5.16	16.97	1.93
2015	0.50	8.50	6.82	-3.58	-5.03	15.43	1.69
2016	0.45	10.95	7.20	-3.78	-5.34	16.32	2.02
2017	0.40	9.50	6.90	-3.51	-5.31	15.73	2.36
2018	0.43	9.65	7.57	-3.41	-4.59	15.57	2.72
Mean	0.47	6.96	6.95	-2.54	-3.78	13.27	1.33
							17.02

This table reports the demand change for a stock moving from the Russell 1000 to Russell 2000 Index, both total and driven by the Russell indices only.^a To get the demand change implied by BMI, the deflated change in BMI (ΔBMI) is scaled by AUM_t/MV_t , the ratio of the total benchmarked assets to the market value of a stock next to the cutoff (band of 100 stocks) in year t . Russell 1000, Russell Midcap, and Russell 2000 columns represent the percentage change in demand corresponding to the assets benchmarked to the respective indices. Computational details are in Appendix A.19. Active and Passive represent the percentage change in demand of active and passive funds. Fraction passive is the ratio of passive demand change to full demand change. The last row shows the mean of 1998-2018.

^aWe report the estimates for stocks added to the Russell 2000 only because those for stocks deleted from it are almost identical.

A.19 Demand Change Computed Using Benchmarked Assets

In this section, we show that using the BMI change is, in concept, analogous to using the change in benchmarked assets used by [Chang et al. \(2014\)](#) but BMI change accounts for heterogeneous benchmarks, which has quantitative implications for the estimate of elasticity.

To evaluate the percentage change in demand, [Chang et al.](#) use:

$$\Delta Demand_{it} = \omega_{i,R2} BA_{R2} - \omega_{i,R1} BA_{R1}$$

$$\% \Delta Demand_{it} = \Delta Demand_{it} / MV_i = \left(\frac{BA_{R2}}{\sum_{R2} MV_k} - \frac{BA_{R1}}{\sum_{R1} MV_k} \right)$$

where BA_j corresponds to the assets benchmarked to index j , $\omega_{i,j}$ – to the weight of stock i in index j , and $\sum_j MV_k$ – to the total market value of stocks in index j . Notice that if only Russell 1000 and 2000 weights were changing, the change in deflated BMI would be exactly that, only scaled by the total equity market at that point in time. So $\Delta BMI_{it} \times Market_t / MV_i$ is equivalent to $\% \Delta Demand_{it}$.

However, when a stock moves across the Russell cutoff, not only does it leave the Russell 1000 and join the Russell 2000, but it also leaves the Russell 1000 Value and/or Growth. It is important to account for the latter. Table 16 shows that Russell Value and Growth indices are even larger than blend indices in terms of the assets benchmarked to them. Moreover, since the Russell Midcap represents the smallest 800 stocks in the Russell 1000, the stock exits it too. The size of the investor base of the Russell Midcap is just as large as that for the Russell 2000. It is therefore surprising that most of the literature studying the Russell cutoff has not taken all these indices into account.

The change in our BMI measure provides the most accurate change in demand for the stock. To illustrate the importance of heterogeneous benchmarks, we will use the detailed assets of Russell indices (we assume membership in S&P and CRSP indices is held constant). A change in demand of a stock moving across the Russell cutoff can be formalized using the weight of the stock in the indices and the assets benchmarked to them:

$$\begin{aligned} \Delta Demand_{it} = & \omega_{i,R2000} BA_{R2,t} + \omega_{i,R2000V} BA_{R2000V,t} + \omega_{i,R2000G,t} BA_{R2000G,t} \\ & - \omega_{i,R1000} BA_{R1000,t} - \omega_{i,R1000V} BA_{R1000V,t} - \omega_{i,R1000G} BA_{R1000G,t} \\ & - \omega_{i,RMid} BA_{RMid,t} - \omega_{i,RMidV} BA_{RMidV,t} - \omega_{i,RMidG} BA_{RMidG,t} \end{aligned}$$

The percentage change in demand is:

$$\begin{aligned}
\% \Delta Demand_{it} &= \Delta Demand_{it} / MV_{it} \\
&= \frac{BA_{R2000,t}}{\sum_{R2000} MV_{jt}} + \frac{Shares_{it}^G / Shares_{it} \times BA_{R2000G,t}}{\sum_{R2000G} MV_{jt}} + \frac{Shares_{it}^V / Shares_{it} \times BA_{R2000V,t}}{\sum_{R2000V} MV_{jt}} \\
&\quad - \frac{BA_{R1000,t}}{\sum_{R1000} MV_{jt}} + \frac{Shares_{it}^G / Shares_{it} \times BA_{R1000G,t}}{\sum_{R1000G} MV_{jt}} + \frac{Shares_{it}^V / Shares_{it} \times BA_{R1000V,t}}{\sum_{R1000V} MV_{jt}} \\
&\quad - \frac{BA_{RMid,t}}{\sum_{RMid} MV_{jt}} + \frac{Shares_{it}^G / Shares_{it} \times BA_{RMidG,t}}{\sum_{RMidG} MV_{jt}} + \frac{Shares_{it}^V / Shares_{it} \times BA_{RMidV,t}}{\sum_{RMidV} MV_{jt}}
\end{aligned}$$

where in the second equality we used the definition of market value weights in Russell indices and where $Shares_i^G / Shares_i$ is the fraction of floated shares of stock i assigned to the growth style by Russell, and $Shares_i^V / Shares_i$ – to value.

Assuming that on average a half of stock shares are assigned to value style,⁸⁹ we can write the percentage change in demand as:

$$\begin{aligned}
\% \Delta Demand_{it} &= \frac{BA_{R2000} + BA_{R2000G} + BA_{R2000V}}{\sum_{R2000} MV_j} - \frac{BA_{R1000} + BA_{R1000G} + BA_{R1000V}}{\sum_{R1000} MV_j} \\
&\quad - \frac{BA_{RMid} + BA_{RMidG} + BA_{RMidV}}{\sum_{RMid} MV_j}
\end{aligned}$$

As Table 15 shows, this percentage change in demand for a stock moving across the cutoff is substantial and time-varying. For the Russell indices only, it ranges between 1.55% to 10.23%. It implies that over 10% of the floated shares of a stock might be demanded in an index reconstitution event due to benchmarking. The table also shows that most of this demand is driven by active funds, though the contribution of passive funds has been rising, reaching 36% in 2018. Intuitively, the full change in demand implied by the change in BMI is very similar, 6.96% on average, deeming our assumption that membership in other indices is held constant correct.

Finally, this analysis allows us to evaluate the quantitative implications of the heterogeneity of benchmarks. For example, if we were to omit the Russell Midcap from the calculation, the average % demand change would be 10.73%. This would imply the estimate of price elasticity of demand of -4.67, significantly higher than -3.03, our main estimate.

⁸⁹Russell uses proprietary stock fundamentals and a proprietary algorithm to assign stocks to value and growth indices. This assignment is performed within the Russell 1000 and Russell 2000 universes separately. In our data, we observe the resulting split: some shares of a stock are assigned to value and the rest – to growth. On average, the split is at 50%, even though we observe pure value or pure growth stocks. Naturally, it mirrors that approximately half of the Russell 1000 or 2000 market value is in value, e.g., $\sum_{R2V} MV_{jt} \approx 0.5 \sum_{R2} MV_{jt}$. Therefore, our simplifying assumptions are realistic. We have also computed the percentage demand change on the actual value-growth splits and got identical implications.

A.20 Benchmarked Assets

Table 16: Benchmarked assets and market capitalization of the Russell indices

	Assets under management, billion US dollars											Float-adjusted market capitalization, billion US dollars		
	Russell 1000			Russell Midcap			Russell 2000			Russell 1000	Russell 2000	Russell 1000	Russell Midcap	Russell 2000

This table reports the mutual fund assets benchmarked to Russell indices by year. Russell 1000 Group represents the total for Russell 1000 and Russell Midcap indices of all styles; Russell 2000 Group – for Russell 2000 indices of all styles. The last three columns report float-adjusted market value of the indices. The last row shows the mean of 1998-2018. All data is as of September.

A.21 Rebalancing Regressions Using a Wider Band

Table 17: Rebalancing of additions and deletions, by benchmark and fund type

Summary of separate regressions on additions and deletions						
Change in the ownership by investor group						
Benchmark Fund type	Stocks ranked < 1000				Stocks ranked > 1000	
	Russell 1000		Russell Midcap		Russell 2000	
	Active	Passive	Active	Passive	Active	Passive
Panel A: Change in ownership share						
D^{R1000}	0.11*** (3.69)	0.09*** (3.31)	0.23** (2.79)	0.10*** (2.98)	-0.47*** (-3.44)	-0.85*** (-4.60)
D^{R2000}	-0.11 (-1.60)	-0.15*** (-3.83)	-0.32** (-2.83)	-0.19*** (-3.49)	0.04 (0.22)	1.07*** (4.32)

D^{R2000}	-0.18*** (-6.08)	-0.32*** (-6.58)	-0.08*** (-4.86)	-0.71*** (-5.80)	0.02 (0.99)	0.72*** (11.48)

This table reports γ_j from estimating (6) in the full sample period (1998-2018). Estimation is performed at group j level (by benchmark and fund type). The coefficients come from separate regressions: on stocks that were in the Russell 1000 (so that D^{R2000} indicates addition to the Russell 2000) or in the Russell 2000 (D^{R1000} indicates deletion) in the previous year. Band width is 500 stocks around the respective cutoff. The dependent variable in panel A is the change in ownership shares in stock i from March to September in year t of the respective investor group. In panel B, it is the direction of the trade of the group (1 for buy, 0 for no trade, and -1 – for sell). In panel C, it is the ownership share in September. In panel D, it is a dummy that equals 1 if the stock is held by the group and 0 if it is not. Regressions in both panel C and D additionally control for the dependent variable in March. All regressions include log total market value ($\log MV$) and all other controls in \tilde{X} . In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.22 Rebalancing in Subsamples

Table 18: Rebalancing of additions and deletions, by benchmark and fund type

Summary of separate regressions on additions and deletions						
Change in the ownership by investor group						
Benchmark Fund type	Stocks ranked < 1000				Stocks ranked > 1000	
	Russell 1000		Russell Midcap		Russell 2000	
	Active	Passive	Active	Passive	Active	Passive
Panel A.1: Change in ownership share - in 1998-2006						
D^{R1000}	0.01 (0.38)	0.03** (2.64)	-0.04 (-0.73)	0.02* (1.90)	-0.28** (-2.40)	-0.43** (-3.20)
D^{R2000}	-0.04 (-0.53)	-0.03** (-2.52)	-0.26* (-2.13)	-0.03* (-1.92)	-0.01 (-0.48)	0.42** (2.71)
Panel A.2: Change in ownership share - in 2007-2018						
D^{R1000}	0.22*** (3.99)	0.29*** (10.13)	0.51*** (5.43)	0.35*** (11.47)	-0.88*** (-4.50)	-2.24*** (-15.31)
D^{R2000}	-0.15** (-2.63)	-0.31*** (-7.69)	-0.12 (-0.93)	-0.36*** (-10.36)	0.26 (1.10)	2.28*** (13.89)

D^{R2000}	-0.28*** (-3.90)	-0.99*** (-3.38)	-0.13 (-1.57)	-0.98** (-3.20)	-0.07 (-1.35)	0.99*** (8.47)
Panel B.2: Trade dummy - in 2007-2018						
D^{R1000}	0.45*** (6.24)	0.51*** (7.93)	0.27** (3.00)	0.74*** (5.79)	-0.54*** (-6.42)	-1.40*** (-7.05)
D^{R2000}	-0.35*** (-5.88)	-1.24*** (-10.09)	-0.29*** (-5.36)	-1.18*** (-6.37)	0.14 (1.36)	0.86*** (17.07)

This table reports γ_j from estimating (6) in the subsamples: 1998-2006 (panels A.1 and B.1) and 2007-2018 (panels A.2 and B.2). Estimation is performed at investor group level (by benchmark and fund type). The coefficients come from separate regressions: on stocks that were in the Russell 1000 (so that D^{R2000} indicates addition to the Russell 2000) or in the Russell 2000 (D^{R1000} indicates deletion) in the previous year. Band width is 500 stocks around the respective cutoff. The dependent variable in panels A.1 and A.2 is the change in ownership shares in stock i from March to September in year t of the respective investor group. In panel B.1 and B.2, it is the direction of the trade of the group (1 for buy, 0 for no trade, and -1 – for sell). All regressions include year fixed effects, log total market value ($\log MV$) and all other controls in \bar{X} . In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.23 Rebalancing Regressions With Year Fixed Effects

Table 19: Rebalancing of additions and deletions, by benchmark and fund type

Summary of separate regressions on additions and deletions						
Change in the ownership by investor group						
Benchmark Fund type	Stocks ranked < 1000				Stocks ranked > 1000	
	Russell 1000		Russell Midcap		Russell 2000	
	Active	Passive	Active	Passive	Active	Passive
Panel A: Change in ownership share						
D^{R1000}	0.08*	0.10***	0.12	0.11***	-0.43***	-0.92***

	(-3.98)	(-4.36)	(-2.05)	(-4.21)	(-0.14)	(12.74)
Panel C: Ownership share						
D^{R1000}	0.07*	0.12***	0.18**	0.13***	-0.27*	-1.01***
	(1.82)	(3.95)	(2.56)	(3.48)	(-1.92)	(-4.75)
D^{R2000}	-0.05	-0.12***	-0.09	-0.14***	0.13	1.10***
	(-1.02)	(-3.85)	(-1.01)	(-3.67)	(0.87)	(4.68)
Panel D: Ownership dummy						
D^{R1000}	0.16***	0.32***	0.05**	0.62***	-0.00	-0.51***
	(5.77)	(8.03)	(2.78)	(5.60)	(-0.45)	(-10.23)
D^{R2000}	-0.18***	-0.27***	-0.05*	-0.68***	0.02	0.66***
	(-4.60)	(-5.33)	(-1.78)	(-5.98)	(1.29)	(11.24)

This table reports γ_j from estimating (6) in the full sample period (1998-2018). Estimation is performed at group j level (by benchmark and fund type). The coefficients come from separate regressions: on stocks that were in the Russell 1000 (so that D^{R2000} indicates addition to the Russell 2000) or in the Russell 2000 (D^{R1000} indicates deletion) in the previous year. Band width is 300 stocks around the respective cutoff. The dependent variable in panel A is the change in ownership shares in stock i from March to September in year t of the respective investor group. In panel B, it is the direction of the trade of the group (1 for buy, 0 for no trade, and -1 – for sell). In panel C, it is the ownership share in September. In panel D, it is a dummy that equals 1 if the stock is held by the group and 0 if it is not. Regressions in both panel C and D additionally control for the dependent variable in March. All regressions include year fixed effects, log total market value ($\log MV$) and all other controls in \bar{X} . In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.24 Value and Growth Indices

We document additional rebalancing patterns disaggregating investor groups by benchmark style (value or growth). When a stock moves from the Russell 1000 to Russell 2000, it also enters the Russell 2000 Value and Growth indices.⁹⁰ In an analysis similar to the previous section, we show that active value funds (inelastically) rebalance value stocks and growth funds rebalance growth stocks.

In order to perform a well-specified test as in the main text, we would need to control for variables that define assignment to value and growth indices. This assignment is not as easy to predict compared to market cap indices. Using a proprietary database of I/B/E/S forecasts, B/P, and sales growth, Russell runs a custom probability algorithm to define a share of stock's market cap as value or growth. Therefore, we cannot ensure the exogeneity of style dummies, e.g., $D^{R2000\text{ Value}}$ and $D^{R2000\text{ Growth}}$, and our results in this section should be viewed as suggestive.

As Table 20 reports, both active and passive funds rebalance in line with their benchmarks. For example, passive Russell MidCap Growth funds buy additions to the Russell 1000 Growth universe and sell additions to the Russell 2000 Growth universe.

⁹⁰Russell methodology is such that most of the stocks belong to both indices, i.e., some part of market value is assigned to value and some – to growth. In other words, a stock is rarely a pure value or growth. Russell has special indices for pure style stocks that are rather small in AUM.

Table 20: Rebalancing of additions and deletions, by benchmark with style and fund type

Summary of separate regressions on additions, deletions, and styles															
Type	Change in the ownership by investor group														
	Active						Passive								
	Russell 1000		Russell MidCap		Russell 2000		Russell 1000		Russell Midcap		Russell 2000				
Benchmark Style	Blend	Value	Growth	Blend	Value	Growth	Blend	Value	Growth	Blend	Value	Growth	Blend	Value	Growth
Panel A: Extensive margin															
D^{R1000}	0.26*** (5.15)		0.11*** (4.52)		0.03* (2.08)		0.35*** (6.60)		0.62*** (5.67)		0.73*** (6.63)		-0.71*** (-15.86)		-0.37*** (-4.78)
$D^{R1000\ Value}$	0.27*** (4.96)		0.12*** (3.03)		0.02 (0.66)		0.66*** (5.95)		0.73*** (6.63)		0.73*** (6.63)		-0.37*** (-4.78)		-0.37*** (-4.78)
$D^{R1000\ Growth}$		0.25*** (4.56)		0.07** (2.74)		0.03 (1.57)		0.56*** (5.79)		0.80*** (8.52)		0.80*** (8.52)		-0.37*** (-4.88)	
D^{R2000}	-0.20*** (-3.54)		-0.10*** (-3.59)		0.11*** (4.77)		-0.35*** (-6.59)		-0.63*** (-5.73)		0.78*** (18.63)		0.78*** (18.63)		0.70*** (5.85)
$D^{R2000\ Value}$	-0.15*** (-3.01)		-0.06** (-2.27)		0.07** (2.56)		-0.43*** (-3.87)		-0.43*** (-3.87)		-0.51*** (-5.24)		-0.51*** (-5.24)		-0.43*** (-5.28)
$D^{R2000\ Growth}$		-0.07 (-1.37)		-0.02 (-0.36)		0.15*** (4.68)		-0.33*** (-4.22)		-0.33*** (-4.22)		-0.43*** (-5.28)		-0.43*** (-5.28)	0.63*** (5.61)

This table reports the differences in rebalancing of added and non-added stocks for the pre- and post-handling sample periods. Estimation is performed at fund group level (by benchmark, style, and type). The coefficients come from separate regressions: on stocks that were in the Russell 1000 (so that D^{R2000} indicates addition to the Russell 2000) or in the Russell 2000 (D^{R1000} indicates deletion) in the previous year. Band width is 500 stocks around the respective cutoff. The dependent variables are changes in the ownership status of stock i from September in year $t - 1$ to September in year t by the respective investor group. All regressions include year fixed effects, log total market value, Russell float factor, 5-year monthly rolling average bid-ask percentage spread, and stock's return over year $t - 1$. t-statistics in parentheses are based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.05; **p<0.01; ***p<0.001.

A.25 Alternative Identification on Ownership Data

Table 21: Active and Passive Ownership

Percentage of firm's common shares held by								
	All active	All passive	Active funds benchmarked to:			Passive funds benchmarked to:		
			Russell 1000	Russell Midcap	Russell 2000	Russell 1000	Russell Midcap	Russell 2000
Panel A: Approach of Appel et al. (2008-2014)								
D^{R2000}	-0.67 (-1.09)	1.82*** (17.34)	-0.113 (-1.40)	-0.907** (-3.14)	0.198 (0.39)	-0.226*** (-12.19)	-0.290*** (-21.64)	2.051*** (12.72)
Panel B: Approach of Appel et al. and our sample (1998-2018)								
D^{R2000}	0.18 (0.80)	0.78*** (4.61)	-0.04 (-1.22)	-0.33*** (-3.93)	0.42** (2.60)	-0.11*** (-3.70)	-0.11*** (-3.30)	0.92*** (4.39)

This table replicates and extends the findings of Appel et al. (2019a). Panel A reports the results for the original sample, and panel B - for the extended one. The dependent variable is the fraction of shares in stock i owned by the respective investor group in September of year t . All regressions include year fixed effects, log total market value ($\log MV$) and its square, float and banding controls as in Appel et al. (2019a). Band width is 500. In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.26 Inelastic Component in Demand, Narrow Band

Table 22: Elastic and inelastic components of change in ownership, narrow band

Change in percentage of firm's common shares held by						
	Active funds benchmarked to:			Passive funds benchmarked to:		
	Russell 1000	Russell Midcap	Russell 2000	Russell 1000	Russell Midcap	Russell 2000
Panel A: Using ΔBMI						
ΔBMI	-0.005 (-1.43)	-0.007 (-1.69)	-0.014 (-1.27)	0.001 (1.07)	0.000 (0.04)	-0.011 (-1.56)
Δbmi_j	0.011 (0.84)	0.041*** (3.56)	0.026** (2.69)	0.520*** (15.01)	0.690*** (23.71)	0.650*** (15.84)
Observations	5,747	5,747	5,747	5,747	5,747	5,747
Within R^2 , %	0.7	2.1	1.3	49.8	65.1	59.3
Panel B: Using ΔBMI quartile						
ΔBMI quartile	0.000 (0.05)	0.000 (0.35)	-0.000 (-0.66)	-0.000 (-0.22)	-0.000 (-1.05)	0.000 (0.71)
Δbmi_j	0.021** (2.09)	0.052*** (4.38)	0.019*** (3.27)	0.503*** (14.75)	0.683*** (18.64)	0.588*** (12.93)
Observations	5,747	5,747	5,747	5,747	5,747	5,747
Within R^2 , %	0.6	2.1	1.3	49.7	65.2	59.1

This table reports the estimates of (7) in the full sample (1998-2018). The dependent variable is the fraction of shares in stock i owned by the respective investor group in September of year t . Panel A reports the results with ΔBMI used to capture the elastic response, and panel B - ΔBMI quartile. Δbmi_j is the change in BMI attributable to group of funds j , e.g., active Russell 1000 funds. All regressions include year fixed effects, log total market value ($\log MV$), and other controls \bar{X} . Band width is 100 around both cutoffs. In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.27 Inelastic Component in Demand, by Tracking Error

Table 23: Elastic and inelastic components of change in ownership, by tracking error

Change in percentage of firm's common shares held by group						
	High-TE active funds benchmarked to:			Low-TE active funds benchmarked to:		
	Russell 1000	Russell Midcap	Russell 2000	Russell 1000	Russell Midcap	Russell 2000
ΔBMI	-0.003 (-1.52)	-0.002 (-0.61)	0.003 (0.63)	-0.001 (-0.43)	-0.002 (-0.64)	0.004 (0.80)
Δbmi_j	0.010 (0.84)	0.030* (2.01)	-0.008 (-0.88)	0.023*** (3.80)	0.064*** (4.05)	0.041*** (4.92)
Observations	10,451	10,451	10,451	10,497	10,497	10,497
Within R^2 , %	1.4	0.7	1.0	0.3	2.3	0.6

This table reports the estimates of (7) in the full sample (1998-2018). The dependent variable is the change in fraction of shares owned by the respective investor group of stock i from March to September in year t . ΔBMI is used to capture the elastic response, and Δbmi_j is the change in BMI attributable to group of funds j , e.g., high-TE active Russell 1000 funds. High tracking error (TE) active funds have an annual tracking error higher than the median value for all active funds with particular benchmark in that year, low-TE active funds – lower. All regressions include year fixed effects, log total market value ($logMV$), and other controls \tilde{X} . Band width is 300 around rank 1000. In parenthesis are t-statistics based on standard errors two-way clustered by stock and year. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.28 Second Stage Results Before and After Introduction of Banding

Table 24: Second stage results, by sample subperiod

Long-run excess return

This table reports the results of the second stage regression for the subsamples: 1998-2006 (Panels A1 and B1) and 2007-2018 (Panels A2 and B2). The dependent variable in Panel A is an average monthly excess return from September in year t over the respective horizon. The dependent variable in Panel B is an average monthly return in the respective period, e.g., 12-24 months after reconstitution. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. Band width is 300 stocks around the cutoffs (rectangular kernel). All regressions include the baseline controls: logMV, a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t-1$. t-statistics based on standard errors with clusters by stock are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

This table reports the results of the reduced form regression for the pre-banding sample period (1998-2006). The dependent variables are excess long-run returns of stock i from September in year t over the respective horizon. Panel A uses all stocks in the band of 100 around the cutoff, Panel B uses same band but excludes stocks moving back to the other index in the relevant horizon, Panel C uses all stocks in the band of 300 around the cutoff, Panel D adds all controls to the specification and sample of Panel C (our baseline), Panel E adds 3-year fixed effects. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. t-statistics based on HAC-robust standard errors with clusters at a stock level are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

This table reports the results of the reduced form regression for the post-banding sample period (2007-2018). The dependent variables are excess long-run returns of stock i from September in year t over the respective horizon. Panel A uses all stocks in the band of 100 around the cutoff, Panel B uses same band but excludes stocks moving back to the other index in the relevant horizon, Panel C uses all stocks in the band of 300 around the cutoff, Panel D adds all controls to the specification and sample of Panel C (our baseline), Panel E adds 3-year fixed effects. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. t-statistics based on HAC-robust standard errors with clusters at a stock level are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

This table reports the validity tests by sample subperiod. We include only stocks that were in the Russell 1000 (Panel A1 and B1) or in the Russell 2000 (Panel A2 and B2) in the previous year. We limit the sample to 300 stocks around the cutoffs (rectangular kernel). Dependent variable is a 3-year average of the respective variable after the reconstitution. All tests include the baseline controls: log total market value, a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t-1$. t-statistics based on HAC-robust standard errors with clusters by stock are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.31 Implications for Cost of Equity

Table 28: Cost of equity and index membership

	Cost of equity

Adjusted R ² , %	22	70	71	70	14	82	83	82

This table reports the results of the reduced form regressions for the firm's cost of equity in the part of the sample where Morningstar data is available (2004-2018). The dependent variable is the average cost of equity in the year after the reconstitution. All specifications include $\log MV$ and other baseline controls, namely: a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t - 1$. We limit the sample to 300 stocks around the cutoffs (rectangular kernel). t-statistics based on HAC-robust standard errors with clusters by stock are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

Observations	309	266	220	184	143	587	504	434	362

This table reports the results of the second stage regression for the subsamples: 1998-2006 (Panels A1 and B1), 2007-2018 (Panels A2 and B2). The dependent variable in Panel A is an average monthly excess return from September in year t over the respective horizon. The dependent variable in Panel B is an average monthly return in the respective period, e.g., 13-24 months after reconstitution. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. Band width is 100 stocks around the cutoffs (rectangular kernel). All regressions include the baseline controls: log total market value, a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t - 1$. t-statistics based on standard errors with clusters by stock are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

Observations	1921	1811	1714	1628	1549	2287	2161	2034	1930	1834
Panel B2: Post-banding (2007-2018)										
\widehat{BMI}_{it}	-0.51*** (-2.60)	-0.21* (-1.58)	0.00 (0.02)	0.02 (0.19)	0.04 (0.38)	-0.14** (-2.30)	-0.06* (-1.32)	-0.03 (-0.95)	-0.02 (-0.68)	-0.02 (-0.67)
Observations	1169	1030	887	752	607	1860	1593	1369	1165	1004

This table reports the results of the second stage regression for the subsamples: 1998-2006 (Panels A1 and B1) and 2007-2018 (Panels A2 and B2). The dependent variable is an average monthly CAPM or market model abnormal return from September in year t over the respective horizon. We include only stocks that were in the Russell 1000 (additions) or in the Russell 2000 (deletions) in the previous year. Band width is 300 stocks around the cutoffs (rectangular kernel). All regressions include the log total market value and the baseline controls: a float factor, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t-1$. t-statistics based on HAC-robust standard errors with clusters by stock are in parentheses. Significance levels are based on a one-sided test and marked as: *p<0.10; **p<0.05; ***p<0.01.

A.34 Empirical Approaches to the Russell Cutoff

Table 31: A summary of empirical methods exploiting the Russell 1000/2000 cutoff

Methodology	Sample	Instrument	Example
Fuzzy RDD	1996-2012	Index dummy	Chang et al. (2014)
Fuzzy RDD with IV (3SLS)	1998-2006	ETF ownership	Ben-David et al. (2018)
IV approach with logMV	1998-2006	Passive IO	Appel et al. (2016)
IV with logMV and band controls	2008-2014	Benchmarked passive IO	Appel et al. (2019b)
IV with ranks	1991-2006	Total IO	Crane et al. (2016)
IV for additions/deletions	1993-2010	Change in the passive IO	Schmidt and Fahlenbrach (2017)
Cohort difference-in-differences	2004-2017		Heath et al. (2018)

This table shows empirical approaches most frequently used to exploit the cutoff between the Russell 1000 and Russell 2000 indices. RDD stands for regression discontinuity design, IO – institutional ownership, 3SLS - three-stage least squares, IV – instrumental variable, logMV – log market value (the ranking variable). The layout is borrowed from Glossner (2018).

A.35 Covariate Imbalance Tests

Table 32: Covariate imbalance tests

	Leverage	ROA	Repurchase	Div. yield	Δ Sales	Lerner	$\frac{Capex}{Sales}$	$\frac{M}{B}$	$\frac{R\&D}{Sales}$	$\frac{\Delta Debt}{Assets}$	$\frac{\Delta Stock}{Assets}$	Assets	Acquisitions	Tobin's Q

D^{RU2000}	0.01 (0.68)	-0.00 (-0.48)	0.00 (1.64)	0.00 (0.52)	-0.24*** (-3.48)	7.85 (1.19)	-0.01 (-1.23)	-0.21* (-1.65)	-3.97 (-1.30)	0.01 (0.74)	-0.02*** (-3.15)	732,667* (1.79)	0.022 (0.66)	-41.453 (-0.98)
Obs	1952	1952	1817	1950	1941	1945	1952	1952	1945	1950	1947	1952	1956	1596

This table reports the covariate imbalance tests by sample subperiod. We include only stocks that were in the Russell 1000 (Panel A1 and B1) or in the Russell 2000 (Panel A2 and B2) in the previous year. We limit the sample to 300 stocks around the cutoffs (rectangular kernel). All tests include the baseline controls: log total market value, a float factor control, a 5-year monthly rolling β^{CAPM} , a 1-year monthly rolling average Bid-Ask Spread, %, stock's return over year $t - 1$. t-statistics based on HAC-robust standard errors with clusters by stock are in parentheses. Significance levels are marked as: *p<0.10; **p<0.05; ***p<0.01.

A.36 Optimized Sampling in Prospectus

Figure 6: An extract from the prospectus of Fidelity’s ZERO Large Cap index fund.

Principal Investment Strategies

- Normally investing at least 80% of assets in common stocks of large capitalization companies included in the Fidelity U.S. Large Cap IndexSM, which is a float-adjusted market capitalization-weighted index designed to reflect the performance of U.S. large capitalization stocks. Large capitalization stocks are considered to be stocks of the largest 500 U.S. companies based on float-adjusted market capitalization.
- Using statistical sampling techniques based on such factors as capitalization, industry exposures, dividend yield, price/earnings (P/E) ratio, price/book (P/B) ratio, and earnings growth to attempt to replicate the returns of the Fidelity U.S. Large Cap IndexSM using a smaller number of securities.
- Lending securities to earn income for the fund.

A.37 Implications of Optimized Sampling for Portfolio Weights

Figure 7: Benchmark portfolio weights vs. optimized sampling weights

This figure illustrates the differences between a pure benchmark portfolio (left) and a portfolio constructed using optimized sampling (right). Horizontal bars represent stocks and their heights represent weights of these stocks in the respective portfolios.
